Series 1. [Entered at the Postoffice, Corvallis, Oregon, as Second-Class Matter.] No. 38.

Incubating and Brooding Chickens.

THESE lessons have covered three important subjects in poultry-keeping, namely, Breeds, Housing, and Feeding. We now take up incubation and brooding. Which of the four is the most important may be open to debate. Suffice to say that in practical poultry-keeping neither one of them is important unless proper attention be given to each of the others. Breeding will count for nothing if the chickens have not been properly raised. It is also a

waste of money to build houses for fowls that have been robbed of vitality in their bringing up; neither will feeding of the best kind overcome the effects of faulty incubation and brooding.

The importance of renewing the flock often by killing off the hens about every two years and raising young stock was emphasized in

Lesson 1 when discussing egg production. The old hens are not profitable egg producers. But in renewing the flock the utmost care must be taken in hatching and raising to preserve in the new flock the vitality of the old. If the health and vitality of the stock may be injured by improper methods of incubation and brooding, and these methods are persisted in year after year, disastrous results will soon be brought about by the very frequency with which the flock is renewed. Decrease in egg production, which we may seek to overcome by frequently renewing the flock, will as certainly result from a gradual lowering of vitality as from keeping the hens till they lose their teeth.

It is the opinion of the writer that there are harder problems to solve, and greater difficulty is encountered by the poultryman, in incubation and brooding than in any other part of the poultry business. It looks "easy" to see a hen "come off" with a brood of thirteen lively chicks and not leave any "dead in the shell" behind, but when we begin to interfere with the business and try to improve on nature's way we are pretty sure to encounter some hard problems. Successful raising of chickens depends very largely on following closely nature's way.

1. Eggs for Hatching Must be Produced by Hens of Good Vitality.—If we study the way of the hen that hatches every egg in the fence corner, we will find this fact: The hen that laid the eggs was not confined in close yards; she had the liberty of the fields. This guaranteed good health and vigor. Eggs laid by such hens will hatch better than those from hens cooped up under artificial conditions. Health and vitality in the hen are transmitted to the chick. Eggs that hatch well come from hens that have good vitality. Chicks that live well come from eggs laid by hens of good vitality. The method of hatching or the method of brooding is not always responsible for eggs failing to hatch and for chicks failing to live or grow well. The parent stock, or the conditions under which the parent stock is kept, are sometimes to blame.

Breeding stock, therefore, should be carefully selected, only those individuals being retained that are up to a certain standard of shape, size, and vigor.

It is not claimed here that lack of vigor in the parents will inevitably be transmitted to the offspring. Parents of apparently weak constitution may breed vigorous offspring. A chicken may have been injured in its raising and show weakness without impair-

ing its value as a breeder of strong healthy stock, but the poultryman cannot afford to retain in his flock fowls showing constitutional weakness. Lack of vigor in the parent stock may not always show in the offspring but it will invariably show itself in smaller egg production and in eggs that do not hatch a high percentage of chicks. There may not be constitutional weakness in the fowls that lay the eggs, but if there is lack of vigor there will be correspondingly few eggs that are fertile and fewer of the fertile eggs that hatch.

This subject has been emphasized in previous lessons and need not be further discussed here.

2. Methods of hatching sometimes responsible for poor hatches and

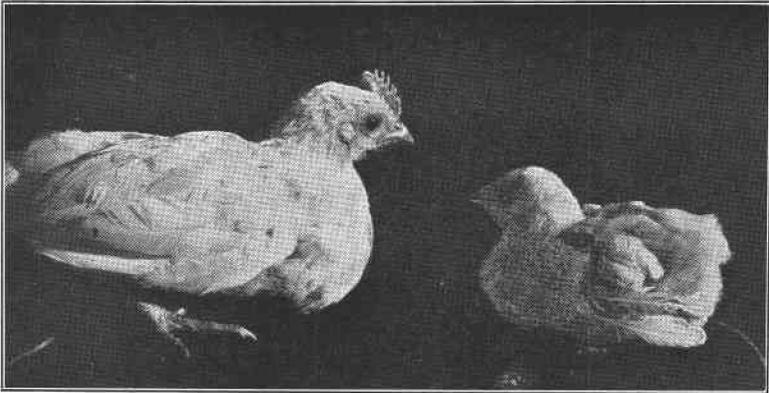

Fig 1. Two chicks of the same age and breed and hatched in the same incubators. Probably a case of "parent stock."

for lack of vigor in the chicks that hatch. Don't always blame the parent stock for poor hatches and for poor chicks. At the Oregon station one method of hatching gave an average of 78.8 chicks from a hundred eggs set, while another method gave 60.6 chicks. When brooded in artificial brooders 90 per cent of the chicks hatched by the first method were alive at the end of four weeks while only 67 per cent of the others were alive. When brooded under hens about 98 per cent of those hatched by the first method were alive at the end of four weeks and only 51 per cent of the others.

While it is true, therefore, that lack of vigor in the parent stock may sometimes account for poor hatches and low vitality in the

chicks that hatch, it is also true that poor methods of incubation may produce the same result.

3. **Methods of brooding** are sometimes faulty and result in a high death rate among the chicks and in impaired vitality in those that grow to maturity.

4. **Feeding and general care** of the chicks is an important part of this subject. It is true that chicks of good vitality will stand a good deal of abuse in the raising; it is true that expensive foods and much labor in feeding are not necessary to get the best results, at the same time to get the rapid growth required of the chicks they must have proper foods.

With the above outline as a guide let us now discuss some of these points more in detail. Omitting further reference to the first topic, let us consider different methods of hatching.

A. *Artificial Versus Natural Methods.*—Nature's incubator is the sitting hen. This does not mean of course that we must always follow nature's way. Modern methods of poultry-keeping are more or less contrary to nature's way of doing things. If left to nature, fowls would roost in the trees and find their own food in the fields and the woods. They would lay their eggs when and where they pleased and hatch and raise the chicks as our China pheasant does. When we want eggs in winter and good market eggs the year around, as well as early spring broilers and winter roasters, we must wean the hen away from nature and put her under more or less artificial conditions. Good poultry keepers have been successful in this. That is why poultry-keeping is a recognized industry of the people. The successful poultryman, however, studies the nature of the hen; he is guided by nature's teachings. When we fail in the poultry business it is very often because we fail to recognize this fact and conduct the business under too highly artificial conditions. This of course applies to breeding, housing and general management as well as to incubation. But we are concerned in this bulletin only with incubation and brooding.

Artificial incubators have been designed to take the place of hens for hatching. To what extent they have superseded them it is impossible to say. Undoubtedly the larger part of the hatching is done in the natural way. Though thousands of incubators are sold every year, it is an open question whether they are as efficient as hens.

During the past few years a great deal of valuable experimental work has been done at different experiment stations on methods of incubation. Experiments at the Oregon Station, reported in Bulletin 100, showed rather conclusively that the hen is more efficient than the incubator. In tests that extended from April to July inclusive with a number of incubators and a great many eggs, the hens hatched more chickens from a given number of eggs than the incubator, and the chicks hatched by hens had greater vitality than those hatched by incubators. The supply of Bulletin 100 being exhausted a summary of the experiments is included here:

1. From 879 eggs set, incubators hatched 533 chicks, or 60.6 per cent.
2. From 279 eggs set, hens hatched 219 chicks, or 78.8 per cent.
3. Eliminating eggs broken in nests, the hen hatched 88.2 per cent of eggs set.
4. The incubators hatched 78.5 per cent of "fertile" eggs, and the hens hatched 96.5 per cent.
5. Eggs incubated artificially tested 22.7 per cent as infertile, while those incubated by hens tested out 11.8 per cent.
6. The incubators showed 16.6 per cent of chicks "dead in the shell", and the hens 2.8 per cent.
7. Chicks hatched under hens weighed heavier than chicks hatched in incubators.
8. The mortality of hen-hatched chicks brooded in brooders was 10.8 per cent in four weeks, and of incubator-hatched chicks 33.5 per cent.
9. The mortality of hen-hatched chicks brooded under hens was 2.2 per cent, and of incubator chicks 49.2 per cent.
10. In other tests the mortality was 46.5 per cent for incubator chicks brooded by hens and 58.4 brooded in brooders.
11. Hen-hatched chicks made greater gain in weight than incubator chicks, whether brooded by hens or brooders.

These experiments were made in the spring and summer months. Incubator chicks hatched in the colder months, for some reason, have greater thrift than those hatched in the warmer months. Chickens hatched in January, February and March are more easily raised than those hatched in the four following months.

Incubators may sometimes be used with advantage early in the season or in the winter months when few hens are sitting and when it is desired to get early chickens or broilers. At such seasons where there is a good market for early spring broilers an incubator with good handling may be profitable. On the average farm, however, where fifty or a hundred fowls are kept, the incubator has no place, nor is it essential on a large poultry farm where a thousand or more fowls are kept. Chickens may be raised in large numbers by the natural method. Even though the artificial method gave equally as good results, the outlay in money in fitting the farm with

incubators and brooders would be much more than is necessary where the hens are used for hatching and brooding.

Cost of Hatching and Brooding Equipment.—To hatch and raise 100 chicks, the cost for equipment and supplies, if artificial methods are used, will be about as follows:

1 incubator 150-egg capacity	\$20.00
2 brooders for 100 chicks	20.00
2 colony houses	20.00
Coal oil for incubator, 5 gals.	1.50
Coal oil for brooders, 7 gals.	2.10
	<hr/>
	\$63.60

By the natural method the cost will be about as follows:

3 combination hatching, brooding and colony coops,	\$24.00
Feed for sitting hens	1.00
	<hr/>
	\$25.00

A good incubator with good eggs and good management will produce 100 chicks from 150 eggs. To raise them artificially, it is usually recommended by incubator makers to divide them into flocks of 50 to 75. In this way two brooders will take care of the 100 chicks for about 6 weeks, after which the brooders may be dispensed with and the chicks raised to maturity in colony growing coops. The equipment, therefore, for hatching and raising 100 chicks by artificial means consists of an incubator, two brooders and two colony houses.

By the natural method of hatching the cost of the incubator is eliminated, hens taking its place. In the same way brooders are dispensed with. Hens may be set and chicks raised in one coop, or house, such as is illustrated in Fig. 2. Assuming that it requires as many eggs to hatch 100 chicks with hens as with an incubator, three coops costing not more than \$8 each will be required, each coop accommodating four sitting hens. By setting the hens at one time the chicks may be given to two hens to brood. The hens need not be included in the cost of the equipment, for they will be worth practically as much after hatching and raising their chicks as before. Neither is it necessary to charge the method with eggs that might have been laid by the hens if they had not been used for hatching. It is doubtful if the hen will not lay as many or more

eggs during the year if she has hatched and raised a brood of chicks than if her natural instincts had not been gratified. By taking a month or six weeks off for hatching in the spring when eggs are cheap, the hen is usually in better condition and will begin to lay earlier in the fall when eggs are a good price. It is not certain, therefore, that the yearly production of a hen will be lessened by allowing her to hatch and raise a brood of chicks.

B. Natural Incubation.—If a proper system be followed chickens may be conveniently and successfully raised in large numbers by the natural way of hatching. One of two methods may be followed. The first requires daily attention in letting the sitters off

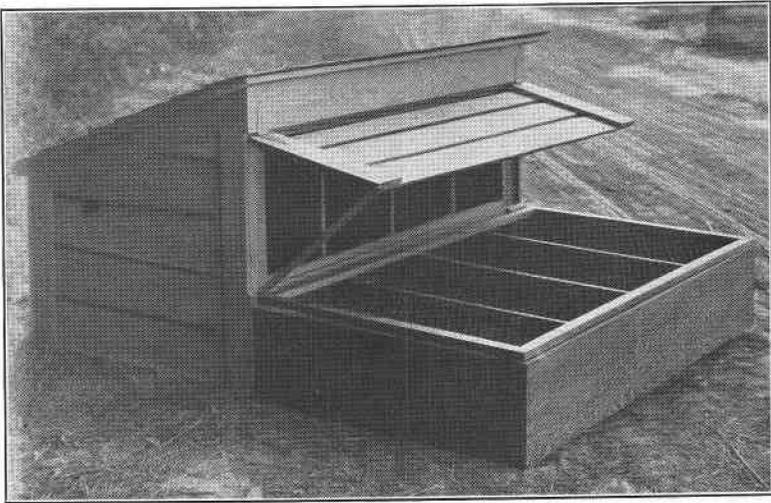

Fig 2. Hen-hatching and brooding coop.

the nest and seeing that they go back again. By the second method the hen leaves the nest and returns at will.

Where it is desired to set a large number of hens, they will be conveniently looked after by making a bank of nests along the side of a poultry house or in some unused shed. The nests should be about 12x12x14 inches in size, made by taking two 12-inch boards for the top and bottom and cutting another 12-in. board into 14-inch lengths for the partitions, then nailing them together, as many as desired. The top of the bottom row will furnish the bottom of the second row, and 4 or 5 rows nests may thus be placed together.

There should be a hinged board at front to confine the sitters. The hens should be let out every day to eat and drink for about fifteen minutes, the length of time depending on weather conditions. Several inches of fine waste hay should be placed in the bottom of the nests. Short-cut straw or clean chaff will answer the purpose. When the chicks hatch about twenty of them may be given to a hen to brood, and the remaining hens may be reset. The hen and chicks may be put in a coop such as is shown in Fig. 3. This will afford them shelter for a month or six weeks, after which a larger coop in which they can be raised to maturity, will have to be provided. Or the small coop may be dispensed with and the hen and chicks transferred direct to the larger coop. A coop the size of that illustrated in Fig 2 is large enough to raise the chicks of two hens, or forty chicks.

The second method of hatching and brooding by hens requires less care on the part of the attendant. We have found it to work well at the Oregon station. One coop serves both for hatching and raising the chicks. (Fig. 2). It serves the triple purpose of an incubator, a brooder and a colony house. A convenient size of coop is 5 feet long and 3 feet wide, with a shed roof 3 feet high at front and two feet at back. It is large enough to divide into separate apartments for four sitting hens. Movable partitions of canvass or burlap are fastened to a 4-inch or 6-inch board at the bottom and to a cross piece at the top. It has an outside run 3 feet long for each hen, covered with wire netting, as shown in illustration. The runs are hooked on to the house and are dispensed with when the chicks are old enough to be given the liberty of the fields. These runs give the hens opportunity for dusting and exercise. By keeping feed and water before them all the time the sitters may be allowed to leave the nests and return at will. In this way very little labor is required in caring for sitting hens. The door on the front is hinged at the top. Underneath this there is a frame of wire netting of one-inch mesh, and in mild weather the door may be kept open. This makes it an open-front house, and during the summer months when the growing chicks use it as a roosting house it will be found that this provision for fresh air is a necessary one. To more conveniently get at the nests or the sitters there is an opening at the back of the coop. The top board which is 10 or 12 inches wide is hinged at the bottom and cut in the center, one door serving for two nests. In dry locations and where the house can be

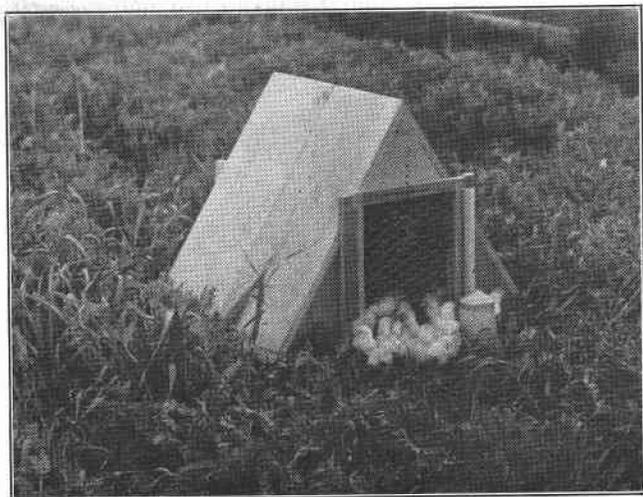

Fig. 3. Coop for hen and chicks.

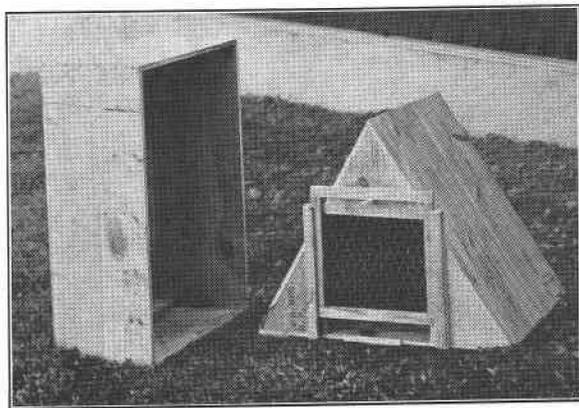

Fig. 4. A brood coop for hen and chicks made out of a shoe box, which is shown on left of picture without cover. The lumber is one-half inch thick. Sides and floor of the coop are 2 feet 6 inches and it is 2 feet deep. Door opening is 10x12 inches. It is made of wire netting to provide the hen and chicks with plenty of fresh air. The door is made by tacking one-inch wire netting on to a frame, which works up and down in a groove. A pin at the top holds the door at any desired opening. In this way the hen may be confined while the chicks may run out and in at will. By closing the door the coop is rat and vermin proof. For convenience in cleaning the back of the coop is made separate and hooked on to the coop. By removing the back the floor may be easily swept or scraped out.

moved to fresh ground occasionally floors are not necessary or desirable. In some localities where rats are a pest a floor will serve to prevent losses of eggs and chicks.

C. A "fireless" and "henless" brooder.—Sometimes it is desirable to raise hen-hatched chicks in a brooder without the hen. We give an illustration of a homemade brooder in Fig. 5. It is made out of a dry-goods box, a little burlap or flannel and a gallon vinegar jug. The box may be 3 to 4 feet long, $2\frac{1}{2}$ feet deep and $2\frac{1}{2}$ feet wide, set on edge. The hover should be about 2 feet square, high enough to put the jug under it. Strips of burlap about 4 inches wide are tacked on to the under side of the hover top, which is made of plain matched boards. These strips hang down all over the chicks, not merely around the edges of the hover, and the chicks nestle among the strips of cloth. The jug is filled with hot water and placed underneath in the center of the hover. If the water is hot a little felt should be wrapped around the jug to avoid burning the chicks. This will also retain the heat longer. During the first week the jug should be refilled night and morning. As the chicks grow older, once a day will be often enough. In warm weather the jug may be dispensed with when the chicks are two weeks old. Later the hover may be removed and the box used for brooding the chicks till they are about 3 months old, as shown in Fig. 6. This brooder will take care of fifty chicks easily. In such a brooder with felt or burlap strips hanging over them it requires very little artificial heat to keep the chicks warm, as they keep themselves pretty warm when all together under the hover. Such a brooder may be used for both hen-hatched and incubator chicks. Fireless brooders of this kind will raise chicks successfully, but a fireless brooder without heat of any kind is not practicable.

Points on Setting a Hen.—The best sitters are the breeds of the American and Asiatic classes. The Mediterraneans, such as Leghorns, Minorcas, Andalusians, are not good sitters. Hens of gentle disposition should be chosen if possible.

Feed the sitters corn or wheat, all they will eat, and provide grit, water and a little green food. Also provide a box of earth for dusting; this should not be too dry.

The hen will usually hatch best in a nest on the ground, but the ground should not be too hard. Cover it with chaff, or short straw or hay. If set on a board floor, put in two or three inches of moist

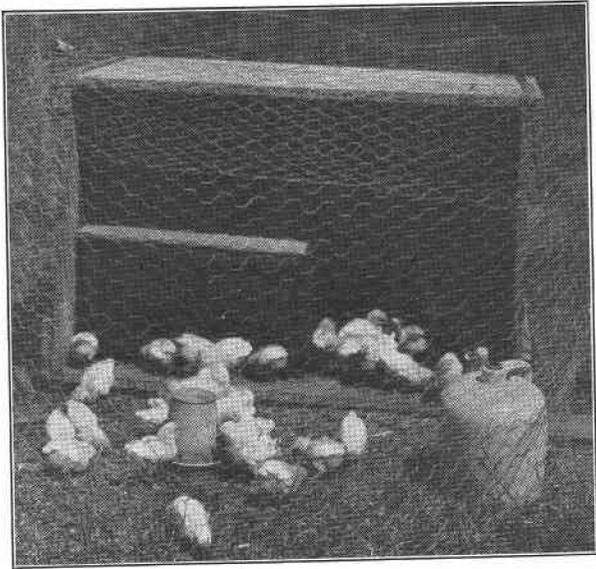

Fig. 5. A "fireless" and "henless" brooder.

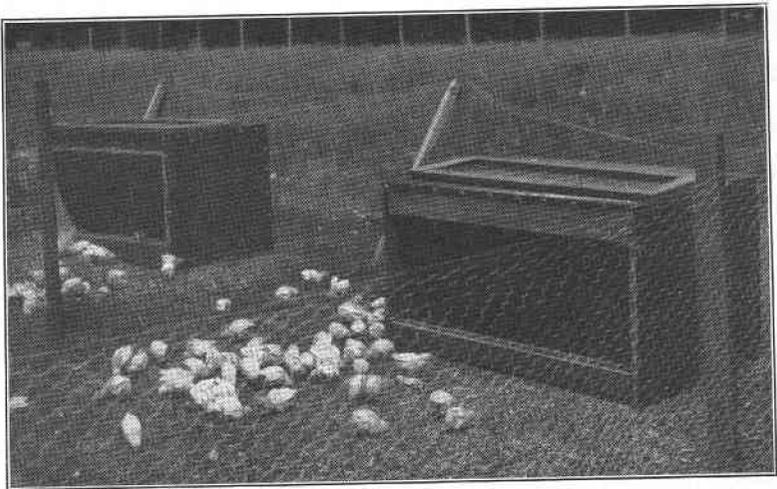

Fig. 6. Brooding chicks in dry goods boxes.

earth, hollow the nest slightly in the center and cover with straw or hay. Planer shavings are also good nesting material.

Dust the hens with insect powder or tobacco dust when setting them. Rub it well into the roots of the feathers. Put a spoonful of the same material, or a moth-ball, in the center of the nest. With this treatment the hen should be free from these pests during the period of incubation if the house or box in which she is sitting is not infested with them. If necessary dust the hen oftener.

After six or seven days of incubation, the infertile eggs should be taken out and saved for the chicks. Rotten eggs should also be removed. If a number of hens are set at one time they may be doubled up after testing; that is, if as many as a setting are tested out, one hen may be reset on fresh eggs. An egg tester may be purchased from a poultry supply house, or a small box may be used in which an electric light globe may be put. In one side of the box cut a hole about the size of an egg. A coal oil lamp or candle may be used instead of an electric light bulb. Testing is done in a dark room or at night by holding the egg to the light at the hole in box. An infertile egg will look clear, just like a fresh egg, only it has a little larger air cell. A fertile egg will be a little dark or clouded. An egg with a dead embryo will be lighter in color than a live one.

One good broody hen will take care of twenty chicks. Another advantage of setting several hens at a time is that the chicks may be "doubled up."

Dust the hen with insect powder when taking her off the nest. Examine the heads of the chicks two or three days after hatching, and if lice are found, rub a little lard on the head and under the throat. If the hen has been properly treated for lice while sitting there will be no necessity for treating the chicks for lice. But watch them.

Moistening the eggs before hatching isn't necessary. The hen attends to that herself.

Keep the hen and chicks on clean grass runs if possible.

If properly managed the hen may be got to laying after being with the chicks two or three weeks.

In warm weather the chicks may be "weaned" when a month old.

D. Feeding the Chicks.—The hen should not be disturbed by feeding till the hatch is complete. As soon as the chicks are all

hatched and dry, hen and chicks should be put in a clean coop with sand on the floor.

It is important that the chicks be given foods that are easily digested. No harm will come to them in permitting them to eat proper food when ready and able to eat. Do not starve the chicks under the mistaken notion that the unabsorbed yolk which the chick dined on before leaving the shell will sustain it in perfect health for three or four days.

As soon as the hen and brood have been put in the brood coop, give the hen a good feed of whole corn and place water where both hen and chicks can drink. At the same time throw a little rolled oats on the sand. There is probably no better "first feed" for the chicks than rolled oats. Being light colored they attract their attention and they soon learn to eat. Cheaper foods may be substituted after two or three days. Bread crumbs soaked in milk is also an excellent "first feed". Chicks may also be successfully started on finely cracked corn or wheat. Hard boiled eggs may be fed with the grain foods. Tested out infertile eggs may be used for this purpose. Instead of boiling the eggs they may be mixed raw with wheat bran. We have found this to give excellent results. For the first day keep the rolled oats, or whatever grain food is fed, on the sand all the time, but after they have learned to eat they should be fed four or five times a day all they will clean up in a short time. There are a number of commercial chick foods on the market which are successfully used for the first feed.

If skim-milk is available give the chicks all of it they will drink. A little chopped lettuce, or other green food should be furnished regularly unless they have access to a grass run. Fine clean gravel or coarse sand in the coop or run will furnish the grit necessary. In the absence of this, chick grit may be purchased at the poultry supply houses.

After two or three days of the "first feed" the feeding may be simplified. There are two points in the feeding of chicks that the poultryman must consider; first, rapid growth; second economy in the ration. After two or three days on the "first feed" cheaper foods may be substituted. Cracked corn or cracked wheat, or both, should form the base of the ration. In addition, the chicks must have animal food, green food and grit. After they are a month old they may be gradually weaned to a ration of whole grain in place of cracked. If the chicks are confined in small yards the cracked

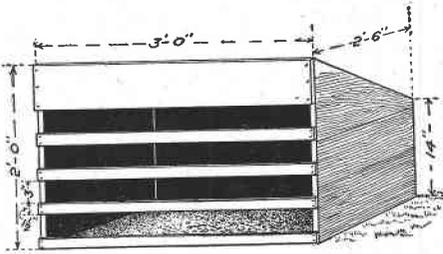

grain should be thrown in a litter of chaff or cut straw to make them exercise. If the chaff is deep enough, enough grain may be mixed in the chaff to last the chicks several days. The litter may be eight to ten inches deep. The important point is to keep the chicks busy and at the same time save in the labor of feeding.

The chicks must have some form of animal food for good growth. Skim milk is hardly concentrated enough to furnish the necessary amount of animal food. It may be fed "clabbered," or better made into a cottage cheese, such as was described in Lesson 3. Lacking the milk, fresh meat scraps may be obtained from the butcher, or beef scrap from the poultry supply house. A good quality of beef scrap may be kept in a box or hopper before them all the time. Fresh cut bones or meat scraps may be fed three or four times a week, all they will clean up. They should have green food all they will eat all the time.

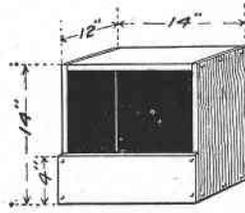

A daily feed of wet mash will be beneficial. Bran and shorts or bran and middlings mixed with skim milk or with cooked potatoes or other vegetables and salted will be relished by the chicks. It will tend also to economy in the ration. Good results, however, may be obtained by feeding entirely on dry foods. Dry feeding, has the advantage of requiring less labor than the wet method, and for that reason many poultrymen follow the dry method entirely.

Chickens may be successfully raised on different rations. No one kind of food is essential. There are some essentials, however, in all foods. The ration must contain grain, animal food, green food, and grit. Chickens won't thrive if lacking either one of the four. Another point, the chicks must have exercise. See that they live an active life.

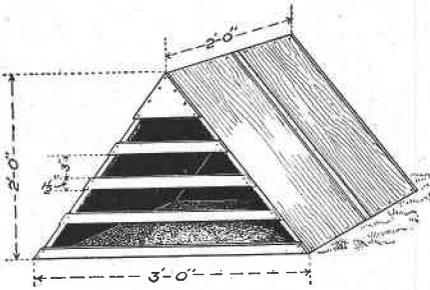

Maturing the chickens.—After the chicks have passed the brooding stage they should have ample roosting quarters and runs. Serious results will follow if they are crowded in small ill-ventilated quarters. They should have abundance of fresh air, without drafts. They will do better roosting in the trees than in a crowded or drafty house. An open shed that will shelter them from the winds and the rains is all that is necessary. The open-front coop, illustrated in Fig. 2 will accommodate thirty to forty chickens till they are mature. With such a house and given free range and some shade the chickens will require very little care during the summer, and they will grow and thrive and be a delight to their owner "when the frost is on the punkin."
