This study re-examines how variations in market power across industries affect the relative number of females and males hired in a given occupation. The study builds upon similar work done by Sharon Oster (1975) to examine the female to male wage differences. Both market power and human capital factors such as education are considered as possible sources of the male/female differentials. The findings show market power in both output and input markets to be a significant factor in most of the occupations analyzed. Educational attainment of females to males is also a significant determinant of the male/female wage and employment differentials across occupations.

# A Re-evaluation of Industry Differences in Male/Female Wages and Employment 

## I. Introduction

Discrimination in the labor market occurs whenever one person is treated preferentially over another even though both individuals are equally productive except for some characteristic such as gender. While each employer may have individual likes or dislikes, discrimination usually involves a common taste or preference on the part of one social group against another, making discrimination a sociological phenomena. Symptoms of discrimination in the labor market are the earnings gap between males and females (wage discrimination) and the differences in the relative number of men and women hired for each occupation (occupational segregation). Although an earnings gap may persist due to legitimate market-related factors such as work experience or education, it may also persist if employers systematically reward women differently than men with respect to pay and promotions. On the other hand, occupational segregation may exist if women choose to enter professions which tend to pay less or if employers systematically hire women for lower paying occupations despite productive capabilities.

Both the male-female earnings gap and occupational segregation exist in the U.S. economy. In 1994, female yearround full-time workers earned only $76 \%$ as much as their male
counterparts, indicating a substantial earnings gap. ${ }^{1}$ Occupational segregation was also evident in 1991 when 55.9\% of all elementary school teachers were female. In comparison, only $5.6 \%$ of all civil engineers, a relatively higher paying occupation, were women. ${ }^{2}$

Differences also exist between industries in the extent to which women are treated differently than men in the labor market. Industry data shows both wage differentials between men and women and differences in the relative number of women and men hired. For example, the ratio of wages of female to male engineers ranges from a low of .45 in the railroad locomotives and equipment industry to a high of 1.98 in the metalworking machinery industry. ${ }^{3,4}$ similarly, the relative number of women engineers ranges from a low of .2 in the paperboard, container and boxes industry to a high of 3 in the fabricated textile products industry. ${ }^{5}$
${ }^{1}$ Employment and Earnings, Jan 1995, Table No. 37, pg. 207.
${ }^{2}$ Statistical Abstract of the United States, 1994, Table No. 629, pg. 392.
${ }^{3}$ The ratio of wages is defined here to be the mean of female wages divided by the mean of male wages. Source: Extracted data from 1990 Census of Population and Housing.
${ }^{4}$ The metalworking machinery industry encompasses the manufacturing of metal machinery products such as bulldozers, machine tools, power driven portable tools, saws, and electric welding wire.

5"Relative" here refers to the number of women divided by the number of men. Source: Extracted data from the 1990 Census of Population and Housing.

Such inter-industry variance in the wage differential and the number of women hired relative to men could reflect differences in the occupational composition of the industries. For example, industries which employ a large number of lowpaid secretaries will undoubtedly have higher relative numbers of women in their work force and also lower wage ratios than industries which consist primarily of high wage engineers. Yet, industry differences exist even for narrow occupational classes. Such differences suggest that the degree of discrimination against women may vary among industries.

In the last thirty years, there have been significant increases in the labor force participation rate of women, changes in labor law, and an overall increase in the education of women. The increase in both the labor force participation of women and the female to male ratio of labor force participation can be seen in Table 1.

Table 1: Civilian Labor Force Participation Rate ${ }^{6}$

| Year | Males | Females | Female/Male <br> Ratio |
| :--- | :--- | :--- | :--- |
| 1960 | $83.3 \%$ | $37.7 \%$ | $49.8 \%$ |
| 1990 | $76.0 \%$ | $57.5 \%$ | $83.0 \%$ |

${ }^{6}$ Monthly data seasonally adjusted
Source: Economic Report of the President, pg.308, pg. 311

The female-to-male participation ratio has almost doubled since the 1960's. The increase in the labor force participation by women undoubtedly increased the number of women hired. (However, if the increase is not uniform across industries, the ratio of females hired to males hired may increase unproportionately for certain occupations.) Over time, the occupational composition of industries may also change as formerly male dominated occupations become infiltrated by women, or vice-versa.

There have also been significant changes in social attitudes and in the law regarding sex discrimination since the 1960's. Changes in the law reflect the changing attitudes of society which should affect the wage differential over time. Table 2 summarizes some of these important changes.

With the change in attitudes and law, firms within industries may no longer be able to practice discrimination; they may be forced to hire more women and close the wage gap. Finally, women have been attaining higher educational levels over time. In 1960, almost twice as many males as females

8Executive Order 11246, 26 Federal Register 2477, 41 CFR parts 60-1 and parts 60-2.
were enrolled in college. Thirty years later, the number of women outnumber the men as shown in Table 3 .

| 1960 | 2.3 | 1.2 |
| 1990 | 6.2 | 7.4 |

If education is, in fact, a measure of productivity, and if all employees within the same industry and occupation have the same quality and years of schooling, then females should be equally productive as males and would thus be expected to receive the same compensation.

Despite these historical trends, evidence shows that wage differentials still occur between men and women within the same occupations and across industries. It is the purpose of this paper to examine male/female wage differentials and the relative number of men and women, across both occupations and industries. The role of market power within a particular industry as well as productivity differences such as education, will be considered as possible determinants of the existing differences.

[^1]This study is an extension of one by Sharon Oster (1975) who examined industry market power as a possible determinant of industry-specific discrimination against women. In her regressions, Oster uses 1960 data and examines the relative number of men and women hired. She finds that the coefficients on the market power variable are of the right sign, but almost all are insignificant. ${ }^{10}$ This paper will reestimate Oster's model using data from 1990 and then build upon Oster's original model to make it more theoretically complete. The remainder of this paper is organized as follows: Section II reviews the literature on male/female labor market differences. Theoretical issues are examined in section III. Oster's empirical model is presented, reestimated and revised in section IV. Section V discusses the data used. Empirical results are presented in section VI followed by conclusions.

[^2]Studies comparing the earnings of men and women have persistently found a pay differential favoring men. Adjusting for both supply and demand side factors reduces the observed differential but does not eliminate it [Hartmann and Treiman (1981), Cain (1986)]. Most economic literature attributes the causes of labor market wage and employment differentials by sex to three major factors (which are often inter-connected): 1) Differences in personal characteristics such as education or experience which lead to differences in quality or productivity as described by human-capital theories,
2) The psychic costs men experience when working with women, "taste discrimination" as discussed for example by Becker (1957), Alchian-Kessel (1962) and Arrow (1971), and
3) Women's relative lack of job choice resulting in a poorer bargaining position and monopsonistic exploitation in the labor market.

Much literature and research has been based on the "human capital" approach which suggests that investment in significant in production. The theory implies that investments in human capital increase labor productivity and thus are one of the more valuable labor characteristics to employers. Most studies find that both education and training
contribute to greater earnings (Eck, 1993). In order for males and females to earn equal wages, both parties must receive the same quality and quantity of education and training, or productivity differences will warrant unequal wages.

Polachek (1978) and Gerhart (1990) find that men and women are unequally distributed across fields of study in college that have different average starting salaries. Blau and Ferber (1991) find that women anticipate considerably lower earnings in subsequent years, even under the assumption of continuous employment. Rudd and Sanik (1983) find that work plans are related to education. Therefore, at least some earnings differentials may be explained by unequal investment in human capital (Malkiel and Malkiel, 1973, Ayers, 1978 and Polachek, 1975).

Supply side arguments also complement the human capital model. For example, it is argued that women are at a disadvantage in career advancement because they do not have the same priorities as men. Due to the traditional division of labor in the family, women may seek jobs requiring less effort (Becker, 1985). It is argued that women are less concerned with professional progress and intellectual challenges and more with comfort, flexible hours and a pleasant work environment [Filer (1985), Daymont and Adriani (1988)]. Lower anticipated earnings for equally qualified women, regardless of their cause, are likely to introduce feedback effects as suggested by Gronau (1981) and Blau \&

Ferber (1986). Thus, women may plan to get less education and spend less time in the labor market in part because of lower expected rewards. These, in turn, further depress female earnings.

Existing studies [Oaxaco (1973)] consistently find that, even after controlling for differences in human capital, there is still a wage gap that might be explained by discrimination. Prejudice or preference for not associating with women under some circumstances may interact with market forces to produce discrimination against women. The form of the observed discrimination may be either unequal numbers of women and men hired, or unequal wages. (Please refer to section III.) Becker (1957) and Alchian and Kessel (1962) have argued that the extent of discrimination by employers is related to the degree of market power such firms possess. ${ }^{11}$ In recent empirical testing of the hypothesis either employment or wage discrimination is presumed to vary by market structure. Typically, the portion of minority employment in an industry is regressed against a variety of industry characteristics including concentration ratio. Most models use the following industry characteristics: percentage of unionization,

[^3]regional variables indicating the percentage of industry employment by geographical area, firm size and occasionally experience and education between majority and minority employees. Almost every study examines the black versus white racial issue. Most studies find a negative coefficient on the concentration measure, but existing empirical tests are ambiguous.

Comanor (1973) finds that estimated measures of racial discrimination are generally higher in more skilled occupations, more profitable industries, and in industries located in large metropolitan areas. He finds discrimination is the greatest in the most profitable industries. Haessel and Palmer (1978) suggest a trade-off exists between employment discrimination and the equalization of wages. They use wages to find that firms in more highly concentrated industries hire fewer minorities than do firms in less concentrated industries. Heywood (1987) shows a measure of wage discrimination to be approximately twice as great for minority workers in concentrated industries as for minorities in unconcentrated industries.

Shepherd and Levine (1973), using a sample of leading firms, find that market share makes little or no difference in the minority employment of white-collar workers. Similarly, Fujii and Trapani (1978) and Johnson (1978) find no systematic relationship between wage discrimination in concentrated and unconcentrated industries.

The results on sex discrimination are not clear. Haessel and Palmer (1978) suggest that firms with more monopoly power tend to discriminate in favor of women, especially in clerical and personnel service occupations. Luksetich (1979) also finds a significant negative coefficient on the concentration measure as do Ashenfelter and Hannan (1986) who examine employment differentials due to sex discrimination in the banking industry. Oster (1975) finds that industry concentration has no effect on the proportion of women employees in an industry.

Interestingly, studies which do not include relative wages in their econometric models find some marginal statistical significance for regional variables with the model [Oster (1975) and Shepherd \& Levin (1973)]. Comanor finds the regional variables to be insignificant in explaining relative wage differentials for minorities.

The final explanation of potential wage discrimination occurs when prejudice is the result of group behavior, rather than its cause (Madden, 1975). Discrimination in this form occurs due to limited job opportunities or immobility in the labor market that has been manifested by male economic power. This case is different from the human-capital theory approach because it suggests women are actually geographically less mobile than men. Luksetich (1979) argues that men collude in
sex discrimination because of their own self-interests. ${ }^{12}$ Likewise, Jacobs (1982) shows that males have power over female occupational choices in many different ways such as place of residence being dictated by the husband's job, legislation that bars women from certain jobs, and male workers who refuse to work alongside female workers. Thus, women may face a monopsonistic employment situation more often than men.

Joan Robinson (1934) developed the case of a discriminating monopsonist, a single buyer of labor who hires labor up to the point where marginal labor cost equals the marginal revenue product. The monopsonist pays workers a wage less than their value contribution to the firm; the wage-value contribution differential measures worker exploitation because it shows that workers are not paid their "worth."

Unfortunately, little empirical evidence exists on how monopsony actually influences the wages of men and women and how sources of economic immobility (e.g. occupational segregation, geographic factors) affect the degree of monopsonistic exploitation among both genders. ${ }^{13}$ However, two major studies show that women's wages appear to be

[^4]significantly more affected by monopsony than men's wages [Gordon \& Morton (1974) and Cardwell \& Rosenzweig (1980)].

There exists no empirical study that develops a model to examine the impact of all of these factors on the female/male wage differential. It is the purpose of this study to fill that gap in the literature.

Recently there has been a wave of inter-industry studies of wage differentials both in the US and other countries. ${ }^{14}$ For example, Luski and Weinblatt (1994) examine concentration ratios and the inter-industry wage structure of the Israeli manufacturing sector and find a positive relationship between wages and the degree of monopolization. Lucifora (1993) finds that both inter-industry and occupational wage differentials in Italy can be explained by either unmeasured workers' characteristics or by compensating wage differentials. In the US, there is a growing body of literature which suggests that concentration generally has a positive effect on wages, especially when the studies have examined the effects of inter-industry wage differences [Dalton and Ford (1977), Jenny (1978), Pugel (1980), Long (1983), Kwoka (1983), Martin (1984), and Brush \& Crane (1989)]. Finally, Bell and Freeman (1991) find interindustry wage dispersion is increasing and attribute about $60 \%$ of the rise to competitive market forces

[^5]such as changes in the demographic and occupational mix of the industrial sectors.

Instead of examining average aggregate inter-industry male/female wage and employment differences, this study looks at these differences for individual occupations across industries. The hypothesis is that male/female differences will be greater for the same occupation when market power is present. This allows for a more precise separation into occupation specific wage differences which may be caused by differences in human capital requirements, and the market power/discrimination causes of male/female differentials.

## III. Theoretical Framework/Model

Becker (1957) first suggested the employer-based model of discrimination in his study of black-white labor market differences. This model can be applied to the analysis of discrimination against women. Discrimination here involves a disutility that occurs when one has contact with a member of the minority. If an individual has a "taste for discrimination," he acts as if he were willing to pay extra to associate with men instead of women. ${ }^{15}$ The concept of a discrimination coefficient $\left(d_{i}\right)$ is used in order to define each employer's individual taste for discrimination. If employers can hire an employee for wage $y$, then an employer is assumed to act as if $y\left(1+d_{i}\right)$ were the net cost of hiring a women. Hence, hiring a women increases net costs of an employer more than hiring a man. The $d_{i}$ represents a nonpecuniary element that can be positive or negative depending upon whether the non-pecuniary element is "good" or "bad.")

The discrimination coefficient can also be measured by the difference between the wage that would be offered to a woman relative to an equally qualified male majority worker. Consequently, the ith employer will have a discrimination coefficient, $d_{i}=Y / Y_{w}-1$ where $Y_{w}=$ the wage the employer is

[^6]willing to offer a woman. Employers who refuse to hire a woman at any wage, have an infinitely large $d_{i}$. If $d_{i}<0$ then the employer is willing to pay more to an otherwise identical female worker and thus discriminates in favor of women workers. A more complete extension of this model specifies $d_{i j}$ where $j$ represents the jth occupation (Hameresh and Rees, 1993). The extent to which employers discriminate differs not only from employer to employer, but also according to the nature of the work. In this case, there may be discrimination in favor of the minority by majority employers. For example, some employers prefer having female secretaries and would be offended by having a male worker doing clerical work. At the same time, the employers prefer not to hire women for executive positions.

As shown in the figure that follows, the demand curve $D_{w}$ shows the total number of minority workers that will be demanded by employers at various wage rates. The shape of the demand curve, $D_{w}$ is determined by arranging the job offers of employers by the size of their discrimination coefficients, $d_{i}$ 's; employers with the smallest $d_{i}$ 's are placed furthest to the left. The horizontal portion of $D_{w}$ represents the labor demand of nondiscriminating employers ( $\alpha_{i}=0$ ) since, if majority and minority workers are assumed to be equally productive, nondiscriminatory employers would be willing to hire minority workers whenever $Y_{w}$ is less than or equal to $Y_{m}$. Beyond the kink point (point $X$ ), the remaining employers have
increasing amounts of prejudice ( $d_{i}>0$ ) and will only hire women at successively lower relative wages. Finally, if some women (or liberal male employers) practiced favoritism towards females, their $d_{i}$ would be negative and the initial part of the demand curve would then lie above 1.0 .

The theory suggests that the size of the wage differential between majority and minority workers depends on two factors. First is the size of the minority group. Other things being equal, the larger the supply of minority workers in the market, the lower their relative wage should be. For example, if the supply curve were $S_{1}$, females could all find jobs with nondiscriminating employers and wages between the two groups would be equal (point $X$ ). With a larger supply of
$S_{2}$, the relative wage of female workers must fall, $Y^{\prime}$ to some point $Z$ in order to induce prejudiced employers to hire women. Note, the wage paid by employers who do not practice discrimination will also be $Y^{\prime}$ since this is where supply and demand are equal.

A second factor in determining the size of the wage differential between men and women is the extent of prejudice that exists among employers. If all employers are nondiscriminatory, then the female to male wage ratio would equal to 1.0 and equal wages would exist in the market regardless of the supply conditions (Kaufman, 1994).

An important implication of Becker's model is that the nondiscriminating firm will have lower labor costs than the discriminators because the nondiscriminating firm will hire equally productive women for lower wages. If a firm discriminates, it will have costs that are greater than the lowest possible costs in the long run in a competitive economy. Thus, the firms will have negative profits and will be forced out of the market via entry of nonprejudiced employers. However, a monopoly has positive economic profits. If a monopolist discriminates, the firm's cost is greater than the lowest cost possible. But, the monopolist can still have profits greater than zero. Barriers to entry keep nonprejudiced employers out. Thus, an increase in market power means there is more likely a potential to discriminate
and firms can continue to discriminate even in the long run (Kaufman, 1994).

Firms may also have an alternate source of market power in the input market that stems from monopsony power and the geographical immobility of female workers. If an industry or a group of industries is the only employer of a particular occupation, then employees have little choice within the occupation but to work with that particular group of industries. Since only a few industries need that specific occupation, firms within these specific industries can exercise more power in the input labor market and may indulge in discrimination. There would be a greater effect if firms within an industry possessed high market power in both input and output markets.

## IV. Empirical Model:

Oster (1975) uses Becker's hypothesis to empirically test the monopoly-discrimination relationship. Oster identifies eight occupations and then examines the relative number of men and women in these occupations across industries. The model Oster uses is as follows:

$$
\left(\frac{W}{M}\right)=\beta_{0}+\beta_{1}\left(\frac{A}{M}\right)+\beta_{2}(M P)+\beta_{3}(G R T)+\beta_{4}(E)+\beta_{5}(W T)+\beta_{6}(S D)+\beta_{7}(N C D)
$$

where $A=$ Dummy with values -- 0 when the number of women $>0$ and 1 when the number of women $=0$
$M=$ Number of men in the industry $i$ in the occupation a
$W=$ Number of women in the industry $i$ in the occupation a
MP = Concentration ratio of industry output
GRT $=$ Growth rate
$E=$ Number of employees per establishment
WT = Percentage of the industry employment in the West
= Number of Employees in industry $i$ in the West/Number of Employees in industry i for the entire us.
SD = Percentage of the industry employment in the South
$=$ Number of Employees in industry $i$ in the South/Number of Employees in industry $i$ for the entire US.
NCD $=$ Percentage of the industry employment in the North Central region
$=$ Number of Employees in industry i in the North Central region/Number of Employees in industry i for the entire US.

In testing the monopoly model, Oster used 1960 data on professional workers since employers are most likely to discriminate against women of higher status who pose the greatest "threat" to their status. Within the class of professional workers, some industries hire more women while others hire less women. Therefore, eight occupations --
accountants, designers, natural scientists, personnel workers, technicians, engineers, draftsmen and managers were chosen because 1) none was a typically female job and 2) the occupations were not overly industry-specific and therefore gave a large sample size.

The sample included a maximum of fifty-six manufacturing industries. Four-firm concentration ratios were used to measure market power and were obtained by aggregating the four-digit ratios by share in employment to the appropriate Census industry level. A dummy variable was used to differentiate between those firms with no women and a lot of men and those firms with no women and only a few men. As the value of $A$ moves from 0 to $1, W$ moves to 0 and $W / M$ decreases; thus the $\beta_{1}$ coefficient is expected to be negative.

On the other hand, the market power coefficient, $\beta_{2}$ is expected to be negative because monopoly power enables economic profits to be greater than zero. An increase in market power (MP) means firms with greater monopoly power do not have to hire as many women. As market power is increased, the ratio of relative number of women to men moves closer to zero.

The growth rate variable (GRT) indicates the change in average employment over a period of time. As the growth rate of an industry is increasing, by definition, the industry is hiring more people. An increase in the numbers hired, along with changes in attitudes, the law and the supply of women,
would suggest that over time there would also be an increase in the number of women hired in proportion to men. This variable is expected to be significant and have a positive relationship with the relative number of women hired making the coefficient $\beta_{3}$ positive. However, for the 1960's data, the opposite is expected to be true; $\beta_{3}$ is expected to be negative because firms in the 1960's did not have the same public pressures that they do in the 1990's. In addition, larger firms before the 1960's faced labor laws that did not pressure establishments to increase the relative number of women hired.

For the 1960's data, the coefficient $\beta_{4}$ (relating to the number of employees per establishment) is expected to be negative. However since then, larger firms are pressured by law to increase the relative number of women hired and in the recent data set, a positive coefficient, $\beta_{4}$ is expected for the number of employees per establishment (average) and the relative number of women hired.

Finally, the South (SD), West (WT), and North Central variables (NCD) were used by Oster in an attempt to compensate for regional variations in the supply of women workers.

Oster's results are shown in Table 4. The market power coefficients are mostly of the expected signs, but almost all are insignificant. The $\mathrm{R}^{2 \prime} \mathrm{~s}$ are low for all eight of the occupations chosen, ranging from 0.0302 to 0.2788 . All growth rate (GRT) and employees per establishment (E) coefficients
are insignificant. Most of the coefficients for A/M, MP, GRT, and $E$ are of the expected signs. While, the regional variables (WT, SD, and NCD) are mostly of mixed signs and on the most part only half of the NCD (North Central) regional variable coefficients are significant.

In order to see how results have changed after thirty years, a re-evaluation of Oster's original work has been conducted using 1990 data. (Refer to Appendix, Section Al for a discussion of the data used for the 1990 sample.) Since, it is not possible to tell precisely what definitions Oster used, the best possible proxy has been found for some variables (see Section V). Heteroskedicity has been corrected for using weighted least squares (wls) as suggested by Kmenta (1986). ${ }^{16}$ Table 5 presents a summary of Oster's model that has been estimated using the more current data. The ordinary least squares results are in Appendix, A8. ${ }^{17}$

The re-estimation shows that the parameter estimates are usually of the expected signs. The $A / M$ term could not be used in many of the models. This is a reflection of the changes in times: due to increased entry of women into traditional male occupations, the dummy variable in most cases was 0 , regardless of the industry. This created a collinearity

## Source: Oster, 1975

*Statistically significant at the .05 level, **at the 0.025 level, ***at the 0.005 level (Rt-tailed tests)
problem and thus the variable could no longer be used. The 1990 results are different than Oster's results in that many more variables are significant. The market power coefficient, $\beta_{2}$, was significant in three of the models: accountants, managers and technicians. Growth rate was significant in four of the models: engineers, managers, personnel service and computer scientists and operators. Similarly, the variable, E, was significant in three occupations: computer scientists and operators, managers, and technicians. Out of the three regional variable, the coefficients of WT and NCD were the most significant in four out of the eight models. Interestingly, market power was significant in accountants and in managers, whereas in Oster's study, market power was significant in personnel workers and draftsmen.

There are several possible problems with Oster's model. First, Oster used the relative number of men and women instead of wage differentials. She did this for two reasons. First, wage differentials by both industry and occupation were not available in 1960. Second, she argued that large, concentrated firms were more likely to have no differences in wages due to standardized wage scales and would thus engage in quantity discrimination. However, this may be incorrect for many firms. Even though the relative number of women may be greater than men, women may be systematically receiving lower wages than men for equally productive jobs that are comparable.

Arguments have been made that employers are able to successfully bypass the law by changing job titles for positions that are comparable in value to pay women less for doing the same job without being detected. This could result in increases in the relative number of women but not in the relative wage. The inclusion of wages into the model would take into account additional information and the ratio of relative wages is used here as the dependent variable. ${ }^{18}$

Oster's model also ignores the power firms possess in the input market (labor market), allowing firms to practice discrimination. Suppose firms in an industry have market power in the output market (a high concentration ratio). Firms within this industry may not be able to discriminate if they have to compete for skilled labor with firms in more competitive industries. Therefore, firms will have to hire both women as well as men, at higher wages otherwise the firm will risk losing their labor supply to other firms. However, firms within an industry may have market power in both the input and output markets. Here firms can indulge in discrimination because of the additional market power.

In this study, it is assumed that the labor market for highly skilled labor is national. It is proposed that a variable defined as the number of employees within a

[^8]particular occupation and industry divided by the number of employees within the particular occupation for the U.S. be added to the model to determine the potential for monopsony power in the input market and its effect on wages.

Finally, Oster's low $\mathrm{R}^{2}$ 's may reflect the fact that she does not correct for heteroskedasticity. A low $\mathrm{R}^{2}$ may also indicate omission of variables. Hartmann and Treiman (1981) cite a number of studies which show women may have been exposed to pre-market discrimination which causes women to receive lower level of education. According to the humancapital theory discussed earlier, education determines productivity and hence determines wages. If this is true within specific occupations, wages for women will be lower due to educational attainment. Hence, in order to accurately examine the portion of male-female wage differential due to discrimination, educational differences within occupations as well as industries must be controlled for. In addition, we correct for heteroskedicity.

Experience is another variable that would add information to the model. If women have less experience than men, relative wages would obviously be lower regardless of discrimination. Unfortunately, data available on experience is not available in the census data being used. The level of educational attainment thus must proxy for a dimension of human capital.

Modified Oster's Model: The model developed here will use wage differentials while trying to capture the effects of pre-
market discrimination as well as market power in both the input and output markets. The goal will be to test whether market power has the hypothesized discriminatory effects on wage differences. The model is as follows:

$$
\left(\frac{Y_{\mathrm{f}}}{Y_{\mathrm{m}}}\right)=\beta_{0}+\beta_{1}\left(\frac{W}{T O T}\right)+\beta_{2}(M P)+\beta_{3}(I C R)+\beta_{4}\left(\frac{E D_{\mathrm{f}}}{E D_{\mathrm{m}}}\right)+\beta_{5}(E)+\beta_{6}(G R T)
$$

where

$$
\begin{aligned}
& Y_{f} / Y_{m}=\text { The relative wage differential of females to } \\
& \text { males } \\
&=\text { Average income of females/Average income of } \\
& \text { males }
\end{aligned}
$$

This variable has been substituted for the relative number of women/men hired which in part will be accounted for by the W/TOT variable.
$\mathrm{W} / \mathrm{TOT}=$ Number of women in industry i, occupation a/ Number of men and women in the industry $i$, occupation a.

This variable is needed to describe the percent of women as compared to men. It has been substituted for the $A / M$ variable to avoid the use of the dummy variable and to instead use a more descriptive variable.

MP $=$ Concentration ratio of industry output

ICR $=$ Input concentration ratio
$=$ Number of all people in occupation $a$ in industry i/Number of all people hired for occupation a for all industries (all i)

This variable has been included to analyze market power in the labor market.
$E D_{f} / E D_{m}=$ The ratio of mean educational attainment of females to the mean educational attainment of males.
where $E D_{f}=$ Sum of YEARSCH $_{f} /$ Number of Females and $E D_{m}=$ Sum of $Y E A R S C H_{m} /$ Number of Males

This variable has been added to capture pre-market discrimination as evident by differences in educational attainment of females to males.
$E=$ Dummy with values -- 0 when the number of employees<15

The variable, $E$ has been changed to a dummy variable to incorporate the changes in law since the 1960's. Employers of small firms (less than fifteen employees) are not subject to the equal opportunity laws as are the large firms.

GRT $=$ Percentage change in the annual average, industry employment between 1980 and 1990. The particular ten year period (between 1980 and 1990) is used to look at long term trends and because by 1980, the data of industry employment will reflect changes in the law. Under the new law, the industry will hire both men and women.

The dependent variable is $Y_{f} / Y_{m}$ which is the ratio of wages of females to wages of males. If $Y_{f} / Y_{m}<1$ then females on an average are paid less than men within industry and occupation. The variables WT, SD, and NCD have been eliminated. Oster found them insignificant and there is reason to expect a change in the regional attitudes towards sex discrimination. In particular, attitudes towards the role of women in the work place have changed since the 1960's. The increase in media and mobility of workers has most likely
contributed to a more homogeneous national attitude towards women.

For $W / T O T$ to increase, the number of women $W$, has to increase relative to the total number of men and women (TOT). If $W / T O T$ increases, more women are hired relative to men. Becker's theory predicts that an increase in the number of women should increase the wage differential if employers are discriminators, ceteris paribus. (As more women enter the industry, the supply curve shifts to the right lowering the wages, suggesting a negative coefficient for $\beta_{1}$.) An increase in W/TOT is consequently expected to result in a decrease in the ratio of female to male wages, $Y_{f} / Y_{m}$. It is expected that the coefficient, $\beta_{1}$ will be negative.

As in Oster's model, a negative relationship is expected between market power and relative wages for discriminatory employers. An increase in market power means firms can continue to pay male labor more and thus the wage differential should be greater.

As discussed above, women's wages may be more affected by monopsony power than are men's wages. Consequently, an increase in ICR should move the wage ratio closer to zero, implying a negative coefficient for $\boldsymbol{\beta}_{3}$.

Human capital theory suggests that even in the absence of discrimination, a positive relationship should exist between the ratio of mean educational attainment and the ratio of wages. (An increase in YEARSCH $f$ and a decrease in $Y^{\text {YEARSCH }} m$
should lead to an increase in $Y_{f} / Y_{m}$.) It is expected that there exists a positive coefficient $\beta_{4}$ between the between the relative educational attainment and wages. Given the upward trend in female education, it is expected that $Y_{f} / Y_{m}$ has increased over time.

Firms with fewer than 15 employees ( $E=0$ ) are not subject to the same law as firms with greater than 15 employees ( $\mathrm{E}=1$ ). Thus, as $E$ moves from value 0 to value 1 , the relative number of women hired by firms is expected to be increased due to the law's requirements only in the absence of discrimination. An assumption can also be made that large manufacturing companies have standardized hiring practices and wage scales and consequently do not discriminate. ${ }^{19}$ Therefore, a positive coefficient for $\beta_{5}$ is predicted between the number of employees and the ratio of female to male.

A positive relationship is expected in the growth of an industry and the relative wages. If the growth rate is positive, it means that the industry is growing and can hire more women relative to men. As these women are hired, the employers will be pressured to pay women higher wages due to changes in times. ${ }^{20}$ Moreover, as an industry grows so does

[^9]the demand for labor. If most men are already hired, discriminating firms may be forced to start hiring women.

Table 6 summarizes the results for the modified model. Again, most of the variables are of the expected signs. This model too has been corrected for heteroskedicity as outlined by Kmenta (1986). The market power coefficient, $\beta_{2}$ is negative as expected and significant in four of the eight occupations: accountants, natural scientist, and technicians. Interestingly, the market power coefficient for ICR, $\beta_{3}$ is significant for the other three out of four models: managers, personnel service, and designers. The coefficient on educational attainment of females relative to men is positive as expected and significant for six occupations. For designers, there is an unexpected negative relation and an insignificant relationship for natural scientists. This is not surprising since the data for natural scientists show the mean educational attainment for males and females to be almost identical at 13.47 years and 13.55 years. The coefficient on $E$ is only significant for designers, indicating that legal changes may have had an impact as hypothesized. The growth rate is significant in managers, natural scientists, and designers.

## v. Conclusion

The data shows the relative number of women is greater than men in almost every occupation (see Appendix, section A9). At the same time, wages for women are lower in every occupation than are men's wages (see Appendix, section A9). Therefore based on relative numbers, it seems females are either given preference over males or the supply of females workers relative to male workers is larger in certain occupations. But, wage discrimination still seems to persist. Consequently, analyzing inter-industry differences provides additional information.

The fact that the inter-industry ratio for the relative number of women to men ranges from $<1$ to $>1$ suggests women are favored in some industries and occupations. But thirty years ago, Oster's study showed that the relative number of men was greater than women. Market power is significant in more of the occupations than in Oster's study. In light of the legal changes it is not surprising to see the growth rate and the number of employees per firm significant in explaining the relative number of females to males hired. The significance of these variables indicates that legal changes may have had an impact in certain occupations. Finally, despite social changes, the regional variables are significant more now than in Oster's model.

Regardless of whether more women are hired than men or vice versa, wage discrimination still persists. That is, for the most part, women are paid less within industry and occupation. This study shows that market power in the output product market does lead to a difference in the ratio of wages for four of the eight occupations. Out of the remaining four, three occupations illustrate market power in the input market as significant. This finding indicates that firms with substantial market power can in fact have some degree of influence over hiring practices especially in regards to compensation as Becker's theory suggests. The policy implication is therefore that competition needs to work smoothly. The fact that the mean educational ratio is significant in six out of the eight occupations suggests that despite social changes in attitudes, much more attention is needed for females before they enter the labor market.

Future research may capitalize on the findings presented here and re-examine specific occupation and industries for an in-dept analysis. Alternatively, future research can use these results to isolate significant variables when studying the relative number females to males hired and their wage ratios within industries. The final goal being to equalize both relative number of females to males and their wage ratios within industries and across occupations.

Appendix

## A1. Data:

The original sample has been taken from the 1990 Census of Population and Housing CD's from the $5 \%$ sample of the Public Use Micro-data Sample using the occupations and industries described below as well as listed in sections A3 and A4 in the Appendix. ${ }^{21}$

Since all occupations used have been professional occupations, taking the differences in physical ability of men and women into account is not important. In order to compare results with Oster and in order to keep a fairly large sample size, the occupations used have been as follows:

1) Accountants and Auditors
2) Engineers
3) Administrative Support and Managerial Occupations
4) Personnel Service Workers
5) Computer Scientists and Operators
6) Natural Scientists
7) Designers
8) Technicians and Related Support Occupations

Economists, lawyers, draftsmen, social scientists, and urban planners and mathematical scientists had to be dropped due to insufficient observations within the manufacturing industries.

[^10]The original sample containing data from the Population and Housing $C D$ was organized on the individual level and had to be aggregated into the industry level. In order to get the data into working condition, all individuals working part time and/or part year were dropped from the sample. ${ }^{22}$ After adjusting for full time, full-year workers, 18,225 individual observations were left in the data set.

The original sample was next separated into two groups: males and females. It was sorted by occupations into the 8 different occupations listed above and the observations from the 57 industries were pooled so the data had the following format:

Men:
Occupation 1:
OBS 1 all individual observations pooled within Industry 1 with variables calculated
OBS 2 all individual observations pooled within Industry 2 with variables calculated
OBS 3 all individual observations pooled within Industry 3 with variables calculated

```
. .
```

OBS 57 all individual observations pooled within Industry 57 with variables calculated

The same format was used to organize the data for women. In the final working sample as shall be explained later,

[^11]the females outnumbered the men in every occupation except Engineers.

All variables were calculated using the Census of Population and Housing Data except for MP, GRT and E. Fourfirm concentration ratios coordinating with the appropriate Census industry level were obtained from the Census of Manufacturing, 1987 for the four digit level. The 1987 figure is the most current available at this time and should be the most accurate means of calculating ratios because as 1) the 1990 industry variable corresponds with the 1987 Census of Manufacturing and 2) concentration is relatively stable over short periods of time.

Since, concentration ratios were only available by 4digit SIC code, they were aggregated in order to get them into the 3-digit form which corresponded to the census of Population and Housing data. The value of shipments in dollars (\$) by 4-digit SIC code was used to calculate a weight by which the 4 -digit concentration ratio was multiplied. Finally, these concentration ratios were aggregated to correspond with the 3 -digit Census code to obtain the variable MP. (The actual data calculation is shown in the Appendix).

Growth rates have been calculated using the differences in annual average employment between the years 1980 and 1990 based on 4-digit SIC codes corresponding to the 1987 SIC codes. A ten year growth rate should be accurate for this
measure because changes in the law take time to implement as well as to enforce. Unlike the data on concentration ratios, annual average employment data was available on the 3-digit SIC level. But, many of the Census codes include several 3digit SIC codes. So, these SIC codes had to be aggregated and weights were used to do this in the same way the concentration ratios were calculated. (Actual data calculation is in the Appendix.)

The average number of employees per establishment (E) was calculated by dividing the number of employees per 3 digit SIC code by the total number of companies within the 3 digit SIC code. (See Section A7 in the Appendix.)

For the relative wage differential of females to males $\left(Y_{f} / Y_{m}\right)$, the variable incomel from the census data was used even though hourly income could be easily calculated using the number of weeks worked and hours worked. ${ }^{23}$ salary income seemed to be a more accurate measure for wage for the following reasons:

1) Since, only professional occupations have been used, most workers probably have been paid in salary form where individuals who work over-time are not compensated directly for the additional time spent. 2) Studies show that individuals consistently overestimate the number of hours they

[^12]work (Morin, 1985). As a result of the above arguments, only full time, full year workers were used.

The final working sample had the following totals for each occupation.

Table 7: Totals of the Final Working Sample

| Occupation | Males | Females |
| :--- | :--- | :--- |
| Natural Scientists | 179 | 400 |
| Accountants and <br> Auditors | 192 | 1513 |
| Designers | 153 | 288 |
| Personnel Service <br> Workers | 130 | 925 |
| Engineers | 1248 | 748 |
| Computer Scientists <br> and Operators | 360 | 1592 |
| Technicians and <br> Related Support | 1149 | 2087 |
| Administrative <br> Support and <br> Managerial <br> Occupations | 2310 | 4951 |

These numbers are quite surprising and at first glance raise the concern for the need to test for discrimination when clearly women outnumber men in almost every occupation. Another puzzling sight is that engineers are the only occupation where men outnumber women. Moreover, for accountants and auditors there are almost eight times the number of women as men!

Since it is fairly certain the sample obtained is of high quality, three other possible explanations are presented here. First as discussed in section 1.3 , the data may simply represent reflections of changing times where women are now obtaining higher paying positions, there exist absences in discrimination against women or where employers are actually favoring women. If either is the case, both Oster's and the modified models should still predict useful results. In the absence of discrimination, relative wages should also be equal or greater than 1.

Second, occupational segregation may have changed over time. It may be that now these professional jobs are not as "high-status, male-oriented" positions as they used to be in the 1960's. This may be possible for designers, since many are employed in typically "female" industries. Yet, it seems unlikely for natural scientists. Again, both models are clearly useful to study the effects of occupational segregation.

The third and most sensible explanation seems to be that the data is indicative of the occupations chosen. Within each broad category, occupations are broken down into different census codes; the number indicates the status, class of workers, type of tasks involved in the job, etc... For example, 009 is not is the "same class" as is 303. In fact, the 000 series consists of higher paid positions that require
higher levels of formal education and training as compared to the 300 series. (Please refer to Appendix, section A3.)

The occupations: personnel service workers; computer scientist and operators; and administrative support and managerial occupations each include mixed suboccupations of both the 000 and 300 series. The large number of women appearing in the sample within these three occupations may be a reflection of broad definitions picked. For instance, within the sample of personnel workers included is census code 328-personnel clerks, except payroll and timekeeping. In 1989, $91.2 \%$ of all employed within this occupation have been female. In contrast, only $52.6 \%$ of all personnel and labor relations managers (also included in personnel service occupations) have been female. ${ }^{24}$ similarly, computer scientists and operators included computer operators (64.2\% of which are female); computer systems analysts, scientists (of which only $32.4 \%$ are female); and operations and systems researchers and analysts (of which $41.1 \%$ are female). ${ }^{25}$ Finally in 1989, females comprised of $80 \%$ of all administrative support, including clerical occupations held. A striking contrast, only $25.9 \%$ of all purchasing managers are

[^13]women. ${ }^{26}$ Both have been included into the broad category of administrative support and managerial occupations.

In retrospect it is evident, that the data sample should have restrained from using a cross of census codes within each occupation. The variable, YEARSCH (a measure of educational attainment differences between males and females) should account for any productivity and skill differences within each suboccupation to allow for the modified model to still be useful in analyzing wages.

A2. Regional Variables (NCD, SD, and WT):

Census divisions are groupings of states that are subdivisions of the four census regions. There are nine divisions which the Census Bureau adopted in 1910 for the presentation of data. They are as follows:

Northeast Region:
Maine
New Hampshire
Rhode Island
New York
Pennsylvania
Vermont
Massachusetts

## A3. List of Occupations:

For additional information about each category in the industrial and occupational and classification system, the individual titles that constitute the category, please refer to Bureau of the Census, 1990 Census of Population and Housing, Classified Index of Industries and Occupations, Sudocs Number: C 3.223/22:90-R-4.

## Census Code

Occupation

Natural Scientists:
069 Physicists and Astronomers
073 Chemists (except Biochemists)
074 Atmospheric and Space Scientists
075 Geologists and Geodesists
076 Physical Scientists, n.e.c
077 Agricultural and Food Scientists
078 Biological and Life Scientists
079 Forestry and Conservation Scientists
083 Medical Scientists
023 Accountants and Auditors
(Includes occupations such as Account Auditor, Bank Accountant, Cost Expediter, Field Auditor, Inspector, Payroll Accountant and Tax Expert.)

## 185 Designers

(Includes occupations such as Commercial Designer, Decorator, Design Maker, Displayer, Dress Designer, Display Manager, Style Advisor and Textile Designer.)

Personnel Service Workers:
008 Personnel and Labor Relations Managers
027 Personnel, Training and Labor Relations Specialists
328 Personnel Clerks, except Payroll and Timekeeping
Engineers:
043 Architects
044 Aerospace
045 Metallurgical and materials
046 Mining
047 Petroleum
048 Chemical
049 Nuclear
053 Civil
054 Agricultural
055 Electrical and electronic
056 Industrial
057 Mechanical
058 Marine and naval architects
059 Engineers, n.e.c.
063 Surveyors and mapping scientists

Computer Scientists and Operators:
064 Computer Systems Analysts and Scientists
065 Operations and Systems Researchers and Analysts
308 Computer Operators

Technicians and Related Support Occupations:
213 Electrical and Electronic Technicians
214 Industrial Engineering Technicians
215 Mechanical Engineering Technicians
216 Engineering Technicians, n.e.c.
217 Drafting Occupations
218 Surveying and Mapping Technicians
223 Biological Technicians
224 Chemical Technicians
225 Science Technicians, n.e.c.
226 Airplane Pilots and Navigators
227 Air Traffic Controllers
228 Broadcast Equipment Operators
229 Computer Programmers
233 Tool Programmers, numerical control
234 Legal Assistants
235 Technicians, n.e.c.

Administrative Support and Managerial Occupations:
303 Supervisors, General Office
304 Supervisors, Computer Equipment Operators
305 Supervisors, Financial Records Processing
307 Supervisors; Distribution, Scheduling, and Adjusting
clerks
007 Financial Managers
009 Purchasing Managers
013 Managers, Marketing, Advertising, and Public Relations
015 Managers, Medicine and Health
017 Managers, Food Serving and Lodging Establishments
018 Managers, Properties and Real Estate
021 Managers, Service Organizations, n.e.c.
022 Managers and Administrators, n.e.c.

A4. List of Manufacturing Industries Used:

This classification is developed from the 1987 Standard Industrial Classification. "n.e.c." is the abbreviation for not elsewhere classified.

1990
Census
Code Industry Category
100 Meat products
101 Dairy products
102 Canned, frozen, and preserved fruits and vegetables
110 Grain mill products
111 Bakery products
112 Sugar and confectionery products
120 Beverage products
121 Miscellaneous food preparations and kindred products
130 Tobacco manufactures
132 Knitting mills
140 Dyeing and finishing textiles, except wool and knit goods
141 Carpets and rugs
142 Yarn, thread, and fabric mills
150 Miscellaneous textile mill products
152 Miscellaneous fabricated textile products
161 Miscellaneous paper and pulp products
162 Paperboard containers and boxes
171 Newspaper publishing and printing
180 Plastics, synthetics, and resins
181 Drugs
182 Soaps and cosmetics
190 Paints, varnishes, and related products
191 Agricultural chemicals
192 Industrial and miscellaneous chemicals
200 Petroleum refining
220 Leather tanning and finishing
230 Logging
231 Sawmills, planing mills, and millwork
241 Miscellaneous wood products
242 Furniture and fixtures
250 Glass and glass products
251 Cement, concrete, gypsum, and plaster products
252 Structural clay products
261 Pottery and related products
270 Blast furnaces, steelworks, rolling and finishing mills
271 Iron and steel foundries
281 Cutlery, handtools, and general hardware
282 Fabricated structural metal products
290 Screw machine products
291 Metal forging and stamping
292 Ordnance

300 Miscellaneous fabricated metal products
310 Engines and turbines
311 Farm machinery and equipment
312 Construction and material handling machines
320 Metalworking machinery
331 Machinery, except electrical, n.e.c.
340 Household appliances
351 Motor vehicles and motor vehicle equipment
352 Aircraft and parts
360 Ship and boat building and repairing
361 Railroad locomotives and equipment
362 Guided missiles, space vehicles, and parts
380 Photographic equipment and supplies
381 Watches, clocks, and clockwork operated devices
390 Toys, amusement, and sporting goods
391 Miscellaneous manufacturing industries

[^14]A9. Inter-industry Ratios by Occupation (Table 9):

|  | Mean <br> $(W / M)$ | Mean <br> $\left(\mathbf{Y}_{f} / \mathbf{Y}_{m}\right)$ |
| :--- | :--- | :--- |
| Natural Scientists | 1.39 | 0.73 |
| Accountants and <br> Auditors | 12.86 | 0.82 |
| Designers | 0.94 | 0.87 |
| Personnel Service <br> Workers | 5.61 | 0.92 |
| Engineers | 0.80 | 0.84 |
| Computer Scientists <br> and Operators | 1.41 | 0.84 |
| Technicians | 2.48 | 0.92 |
| Managers | 2.62 | 0.63 |

where $\operatorname{Mean}(W / M)=\frac{\sum_{\mathrm{i}=1}^{\max }\left(\frac{W}{M}\right)}{\text { number of industries }(i)}$
and

Mean $\left(Y_{\mathrm{f}} / Y_{\mathrm{m}}\right)=\frac{\sum_{\mathrm{i}=1} Y_{\mathrm{m}}}{\text { number of industries }(i)}$

[^0]:    ${ }^{7}$ Hill, pg. 51, 52 and Player, pg. 19, 20.

[^1]:    ${ }^{9}$ Statistical Abstract of the United States, 1994, Table No. $231, \mathrm{pg} .156$. Data for college represent degree-credit enrollment.

[^2]:    ${ }^{10}$ For the market power coefficients, a negative sign is expected.

[^3]:    ${ }^{11}$ Oaxaco (1973) applied Becker's theory and pioneered the residual method of measuring market discrimination. Using the residual approach, the wage gap is decomposed into 1) the earnings gap that the minority receives in the absence of discrimination given their set of income-earning characteristics and 2) the unexplained "residual" amount represents the portion of the earnings gap which occurs due to market discrimination and cannot be attributed to productivity differences.

[^4]:    ${ }^{12}$ This may or may not include the disutilites men experience when working with women.
    ${ }^{13}$ Most studies center on monopsonistic discrimination with in a specific industry and a regional labor market (Landon and Baird, 1971, Malkiel and Malkiel, 1973, Hoffman, 1976, Ferber and Kordick, 1978, Luizer \& Thorton, 1986, and Monk-Turner and Turner, 1994).

[^5]:    ${ }^{14}$ Most studies use manufacturing industries because the data is available for industries in the manufacturing sector and is well suited to test the regression models (Jones and Walsh, 1991).

[^6]:    ${ }^{15}$ The employer may be willing to pay either directly or in the form of reduced income (Becker, 1971).

[^7]:    ${ }^{16}$ Oster did not correct for heteroskedicity in her original work, even though at least one form of heteroskedistic variance existed.
    ${ }^{17}$ The ordinary least squares results are provided for a true comparison against Oster's results; her original work did not correct for heteroskedicity.

[^8]:    ${ }^{18}$ Becker's original model called for using the relative number of men and women instead of wages because in the long run, only competitive, nondiscriminatory firms would be able to exists. In the long run, wages would be equal. (Becker, 1957)

[^9]:    ${ }^{19}$ It is curious to also ponder who really is the employer in such large manufacturing firms-many managers or a few discriminatory employers.
    $20^{\text {However, }}$ the following argument could apply here too: as companies hire more women, they may change job titles or hire women for different occupations.

[^10]:    ${ }^{21}$ In order to do this, the Ascii files from the $C D$ 's were transferred to a temporary directory at an Anonymous FTP site from which a SAS program ran and extrapolated the original sample. A maximum number of 57 manufacturing industries on the three digit industry level were used on which there was data available for both growth rates as well as concentration ratios. All miscellaneous industries have been eliminated.

[^11]:    ${ }^{22}$ All individuals working less than 34 hours a week and less than 47 weeks a year were dropped.

[^12]:    ${ }^{23}$ The variable called Incomel=Wages or Salary Income in 1989 (signed) was taken from the 1990 Census of Population and Housing.

[^13]:    ${ }^{24}$ Statistical Abstract of the United States, $1991, \mathrm{pg}$. 395-397, table no 653.
    ${ }^{25}$ ibid.

[^14]:    *Statistically significant at the .05 level, **at the 0.025 level, ***at the 0.005 level (Rt-tailed tests)
