SEDIMENT TRANSPORT IN STREAMS IN THE UMPQUA RIVER BASIN, OREGON

--

By C. A. Onions

--

ABSTRACT

This report presents tables of suspended-sediment data collected from 1956 to 1967 at 10 sites in the Umpqua River basin. Computations based on these data indicate that average annual suspended-sediment yields at these sites range from 137 to 822 tons per square mile. Because available data for the Umpqua River basin are generally inadequate for accurate determinations of sediment yield and for the definition of characteristics of fluvial sediments, recommendations are made for the collection and analysis of additional sediment data.

INTRODUCTION

The Umpqua River basin is noted for its beautiful, rugged scenery and streams of fresh, clear water. In the past, there has been little concern for the occasional turbidity of the normally clear streams of the basin. In recent years, however, because of the increased use of the basin for recreational and industrial purposes, the following questions have arisen: Does the turbidity represent a significant quantity of sediment and is this quantity increasing? Have the effects of logging, agriculture, forest fires, and recent floods increased erosion in the basin and thus increased the turbidity and sediment discharge of the streams? Are spawning areas of anadromous fish being endangered by sediment deposition? Will expected increase in population and industry introduce new sedimentation problems? Could sedimentation adversely affect existing and proposed engineering structures? It is with these questions in mind that the data and results of computations in this report are presented.

Sediment data are vital in water- and land-use planning and in the design of related engineering structures. For example, knowledge of the sediment characteristics of streams, principally the quantity and particle size of sediment in transport, is necessary to estimate the space needed for deposition of sediment in proposed reservoirs. Concentration of suspended sediment is a major factor in the design and operation of water-supply treatment plants.

Recognizing the need for fluvial-sediment data, the Douglas County Water Resources Survey, under the direction of Ben B. Irving, succeeded by Charles S. Collins, conducted a sediment investigation in the Umpqua River basin from 1956 to 1967. The investigation included the collection of suspended-sediment samples one to four times per month at 10 gaging stations in the basin. The samples were collected with a U.S. D-43 suspended-sediment sampler by personnel of Douglas County. Analysis of samples for sediment concentration was performed for the county at Oregon State University. Discharges at the gaging stations at the time of sampling were computed and furnished by the Douglas County Water Resources Survey.

The purpose of this report is to present the results of sediment-discharge measurements obtained by the county during the investigation and to summarize the results of computed sediment yields. This report was prepared by the Geological Survey at the request of Douglas County Water Resources Survey, using data available as stated above.

DATA AVAILABLE

Published data on sediment transport of Umpqua River basin streams are almost nonexistent. The data obtained by the Douglas County Water Resources Survey consist of periodic suspended-sediment discharge measurements at 10 gaging stations from 1956 to 1967 (fig. 1). Sediment discharges were computed from suspended-sediment concentrations and water discharge for the time of sampling. All these data are tabulated in table 1. The maximum and minimum observed suspended-sediment concentrations and discharges for each station listed in table 1 are given in table 2.

COMPUTATIONS

Suspended-Sediment Discharge and Yield

Data presented in table 1 provide a basis from which to estimate the quantity of suspended sediment transported by the streams and the relative sediment yield from the subbasins within the Umpqua River basin. Results of computations of average annual suspended-sediment discharge and yield for each sampling site are given in table 2.

The procedure used to compute annual suspended-sediment discharge consisted of: (1) relating observed suspended-sediment discharge to water discharge by correlation methods suggested by Colby (1956), and (2) relating sediment discharge to streamflow duration as suggested by Miller (1951).

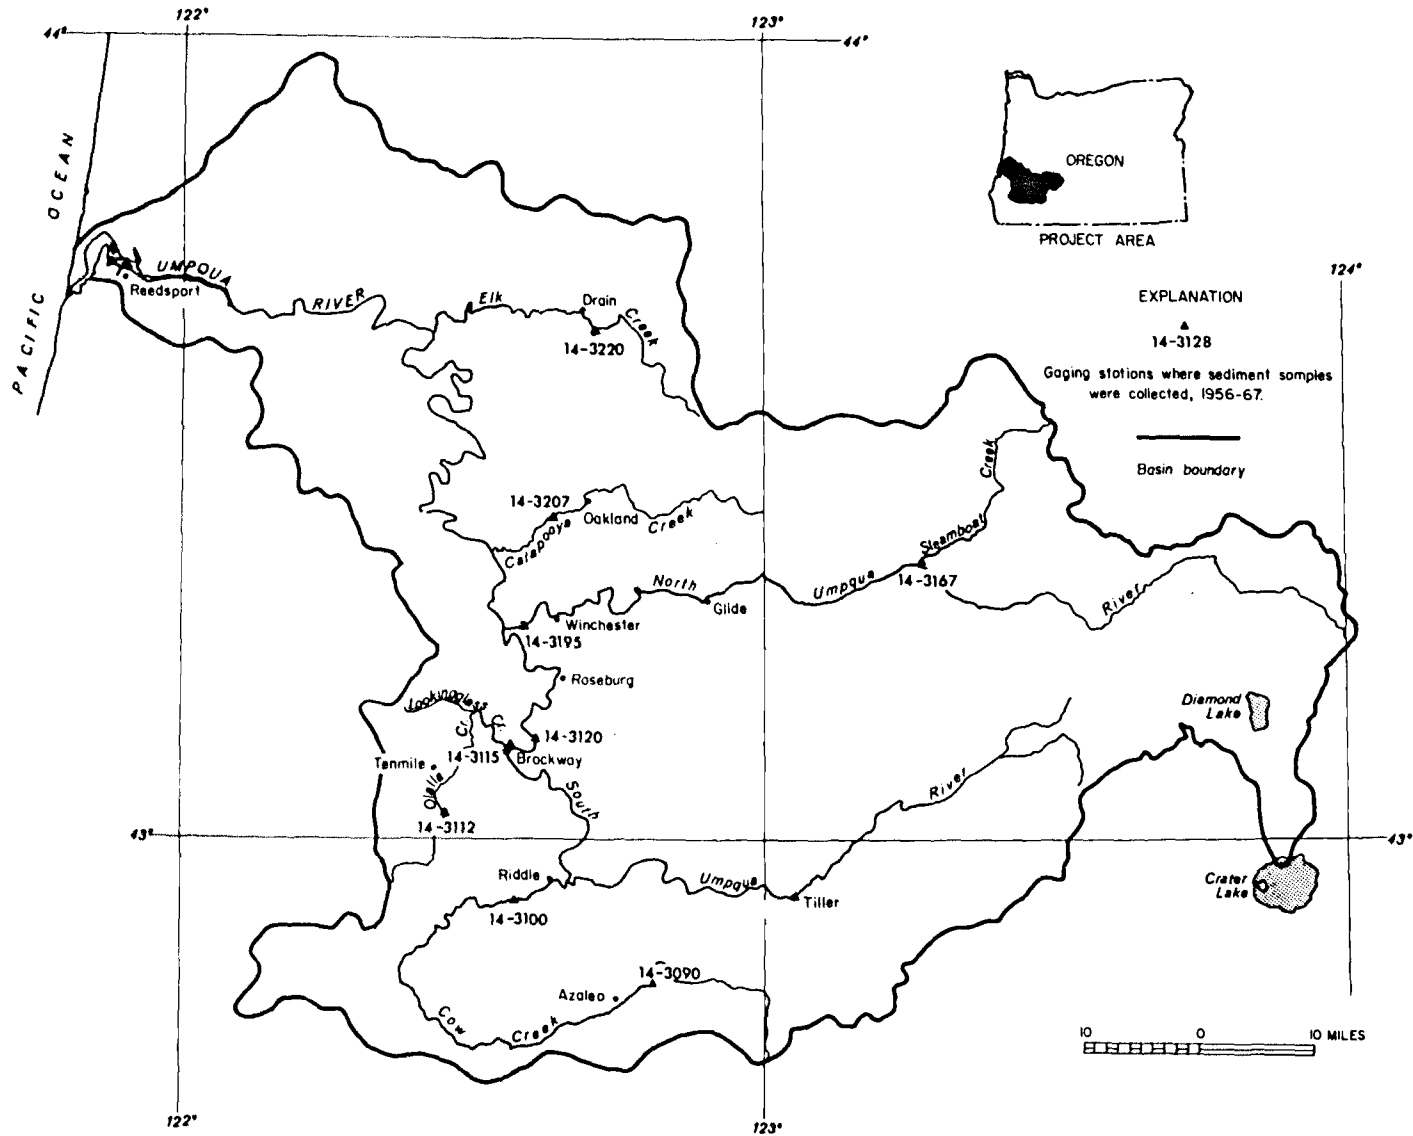

Figure 1.--Suspended-sediment sampling sites in the Umpqua River basin.

The reliability of the computed mean annual suspended-sediment discharge depends on how well the relationship of sediment discharge to water discharge is defined for the full range of flow. Definition for high flows is of particular importance, as demonstrated by sediment records for Flynn Creek, a small stream in the nearby Alsea River basin. For this stream, 85 percent of the annual sediment discharge occurred in a 5-day high-flow period during the winter of 1965. Because of the large sediment yield during this 5-day period, the annual sediment discharge for Flynn Creek in 1965 was greater than that for the 6 previous years combined.

As no special effort was made to obtain sediment-discharge measurements in the Umpqua River basin during periods of high flow, the high-flow end of many of the water-sediment discharge relationship curves is poorly defined. Accuracy of the annual suspended-sediment discharge for South Umpqua River at Tiller and Olalla Creek near Tenmile is considered to be fair because relationship curves for these two stations are well defined at low and medium flows and fairly well defined at high flows. The relationships for the other stations are well defined for low and medium flows but are poorly defined for high flows.

Weighted-Mean Concentration

As a means of comparing the suspended-sediment concentration at the 10 sites, the annual weighted-mean suspended-sediment concentration was computed and is shown in table 2. The weighted-mean concentration values shown were computed by dividing the mean annual suspended-sediment discharge by the mean annual water discharge and multiplying the result by a conversion factor to convert the units to milligrams per liter. The computed values ranged from 44 mg/l (milligrams per liter) for Steamboat Creek near Glide to 397 mg/l for Cow Creek near Riddle. The weighted-mean concentrations are, of course, no more reliable than are the computed average annual suspended-sediment discharge and annual water discharge from which they were derived. However, they do indicate the streams that on the average carry the highest and lowest concentrations of suspended sediment.

SUMMARY AND RECOMMENDATIONS

The results of computations indicate that mean annual sediment yields of 10 subbasins in Douglas County ranged from 137 to 822 tons per square mile. However, the observed suspended-sediment data were insufficient to define accurately the water-sediment-discharge relationships needed for reliable computation of sediment yields. For this reason, the yields indicated in table 2 should not be considered as accurate measures of the relative sediment yield of each subbasin.

In the future, at some sites it may be desirable to collect data at more frequent intervals and of greater variety. Refinement of suspended-sediment yields will require additional sediment-discharge measurements, particularly during high flows. At some sites, bedload discharge, which was not considered in the computations, could be a sizable portion of the total sediment discharge. Data should be obtained from which computations can be made to determine the significance of bedload at the sampling sites. Because of its importance in sediment transport and deposition, data on particle-size distribution of suspended and bed material should be obtained.

GLOSSARY OF TERMS

The sediment terms used in this report are defined as follows:

Bedload is the sediment (1) that moves by sliding, rolling, or skipping on or very near the streambed, or (2) that is moved by tractive or gravitational forces, or both, but at velocities less than those of the adjacent flow.

Discharge-weighted mean concentration is the theoretical sediment concentration if all the water and sediment passing a section during a time interval were mixed. Concentrations are expressed in milligrams per liter.

Particle size is the diameter, in millimeters, of suspended sediment or bed sediment. A classification recommended by the Subcommittee on Sediment Terminology of the American Geophysical Union defines a particle having a diameter of less than 0.004 mm (millimeter) as clay, between 0.004 and 0.062 mm as silt, and between 0.062 and 2.0 mm as sand.

Sediment discharge is the quantity of sediment that is carried past any cross section of a stream in a unit of time. Basically, sediment discharge is made up of two components, suspended-sediment discharge and bedload discharge.

Sediment yield is the sediment discharge from a unit of drainage area, generally expressed in tons per square mile.

Suspended sediment is the sediment that at any given time is maintained in suspension by the upward components of turbulent currents or that exists in suspension as a colloid.
