AN ABSTRACT OF THE THESIS OF

MUSA GHANNAM for the degree of MASTER OF SCIENCE

in PHARMACY presented on APRIL 30, 1981

Title: CHELATING AGENTS IN THE DRUG DOSAGE DESIGN OF IRON PREPARATIONS

Abstract approved: Redacted for Privacy

Dr. James W. Ayres

The role of iron in the body is well known for it is a component of hemoglobin, myoglobin, cytochrome, enzyme catalase and peroxidase. Iron deficiency anemia is widespread among vulnerable groups in industrialized societies and in the general population of tropical developing areas. In the United States there are ten million women with no iron reserves to meet the physiological needs of menstruation and pregnancy.

The normal diet has five times the total amount of iron needed to maintain iron balance but, unfortunately, less than ten percent is absorbed. The absorption of iron has been increased by combining it with reducing agents such as ascorbic acid. Also it was found that protein uptake is necessary for adequate iron absorption.

Increase in absorption was noted when iron was combined with chelating agents. It was suggested that these chelating agents bind iron strongly, forming a stable ring

complex which seems to be necessary to maintain it in a soluble and permeable form.

The purpose of this thesis research was to determine the effect of amino acids on iron absorption. The amino acids were glycine, l. proline, d.l. tryptophan, l. asparagine, d.l. alanine, d.l. phenylalanine, d.l. leucine, serine, d.l. methionine, and l. isoleucine. Ferrous sulphate was combined with each of the amino acids in a molar ratio of 1:2. Iron-59 was used as a tracer. At various time periods after oral administration to rats, blood samples were collected from the rats' toes. At the end of four hours, the animals were sacrificed and liver, kidney, muscle, heart and brain samples were taken from the animals. All blood and organ samples were counted using a solid scintillation counter.

All amino acids increased iron absorption, but the increase was most notable in asparagine, and then glycine. No correlation was found between stability constants of iron with amino acids and initial rate of absorption or area under the curve. In the organs, iron was found mostly in the liver. Lesser amounts were found in the heart and kidney, and very small amounts in the muscle and brain.

Glycine - iron and control tablets were prepared using the direct compression method. Glycine was chosen rather than asparagine because it is much cheaper. These tablets were activated in the OSU TRIGA Reactor for four hours with

a neutron flux of $3x10^{12}$ neutron/cm^2/sec.

These tablets were administered to groups of four rabbits. Blood samples were collected from their ears using the same sampling times as for rats. At the end of four hours the animals were sacrificed and organ samples were taken from the animals. All these samples were counted as before. Results were analyzed using PROPHET[1] and show that iron is absorbed much better when administered with glycine than when administered alone.

ACKNOWLEDGMENTS

I would like to express my deepest appreciation to Dr. J. W. Ayres who was an excellent advisor throughout the time of study at Oregon State University.

Grateful appreciation to Dr. J. M. Christensen for his help to complete the project.

Special thanks to the Graduate Committee for their helpful comments.

My deepest gratitude to the Nuclear Safety Committee at Oregon State University and the staff members at the Radiation Center who made this project possible.

CHELATING AGENTS IN THE DRUG DOSAGE DESIGN OF IRON PREPARATIONS

I. INTRODUCTION

Statement of the Problem

Iron-deficiency anemia is widespread among vulnerable groups in industrialized societies (1) and in the general population of tropical developing areas. In the United States there are five million women with iron deficiency anemia while ten million have no iron reserves to meet the physiological needs of menstruation and pregnancy (2, 3). In Central America, 15% of the total non-pregnant population and 24% of pregnant women at term are anemic based on low serum iron and percent saturation of total iron binding capacity which are associated with anemia (4, 5).

The capacity of the body to excrete iron is very limited and therefore, the iron content of the body must be regulated by changes in iron absorption. For adult males, the normal daily loss of iron is 0.6 mg from the gastrointestinal tract, 0.2 mg from the skin and 0.1 mg via the urinary tract, totaling 0.9 mg daily. The menstruating female loses an additional 0.4 mg per day averaged over a month, to give a daily total loss of 1.3 mg (6). Absorption of these amounts is therefore sufficient to maintain iron equilibrium. However, the

recommended dietary allowance of 18 mg iron daily for women during the reproductive years is not always achieved and with a typical intake of 10-11 mg (1, 6) in the United States a woman must absorb 12-13% of the daily intake to maintain iron equilibrium, whereas the male obtains sufficient bodily iron content by absorbing 6% of the customary intake of 16 mg iron daily. This leaves the woman with less reserve capacity for increasing absorption still further to the maximum of 25% in order to meet added demands, such as pregnancy, and to maintain adequate iron stores. (6).

The standard dosage form available on the market contains ferrous sulphate (7). There are side effects associated with all dosage forms containing iron. These include nausea and gastrointestinal irriations (8).

It has been proposed that since amino acids have a chelating effect upon iron, then there is the possibility that iron absorption might increase if iron is administered with amino acids (9). Kroe et al. (9, 10) used phosphate buffer in experiments to study the effect of amino acids on iron absorption. The results may not be quantitatively correct since phosphate decreases iron absorption both in vivo and in vitro (11), which confounds the results (9, 10).

The only iron chelated tablets available are those produced by Fibertone and Hudson Companies (12). Iron in

these tablets is chelated to protein molecules. Unfortunately, there is no data available about these products. Also, the absorption of iron has been increased by combining it with reducing agents such as ascorbic acid (13-15) and iron with ascorbic acid tablets are also available (12).

Purpose of the Study

This study was initiated in order to formulate an oral iron preparation that has high absorption. The effects of ten amino acids on iron absorption were tested. The amino acids are glycine, l. proline, d.l. tryptophan, l. asparagine, d.l. alanine, d.l. phenylalanine, serine, d.l. methionine, d.l. leucine and l. isoleucine. Iron-59 was used as a tracer. Solid scintillation was used for counting.

The study entailed:

1. The determination of stability constants for the above mentioned amino acids and iron.
2. The effect of these amino acids on the absorption of iron, tested on groups of six rats. Blood and different organ samples were counted. The results were analyzed for correlation with the stability constants of the amino acids and iron.
3. Tablets containing iron and an amino acid were prepared. The amino acid of choice was the one which

increased iron absorption most. Control tablets were also prepared.

4. The above tablets were activated at the OSU TRIGA reactor.

5. These activated tablets were given to groups of four rabbits. Blood and organ samples were counted. Results were compared.

II. THEORY

Iron

Distribution and Types of Iron in Nature

Iron is widely distributed in the animal body. Iron is easily oxidized or reduced, and thus is found as a minute but vital part of certain enzymes concerned with electron transfer (the cytochromes, cytochrome oxidase, succinic dehydrogenase, xanthine oxidase). Normally, about 70% of human body iron is functional or "essential" iron (i.e., in hemoglobin, myoglobin, and intracellular iron containing enzymes) and 30% is storage or "nonessential" iron (i.e., in hemosiderin and ferritin). In women, the storage reserve tends to be less than half that in men (8).

Foods high in iron content include organ meats (liver, heart), wheat germ, egg yolks, meat, fish, milk and milk products and most nongreen vegetables (7, 8).

Quantitative Significance of Iron in the Body

In the adult man there is 4-5 g of iron. This makes iron one of the most important metals in mammals (see Table 1). Other biologically significant heavy metals are found in smaller amounts (11). The demand for iron varies during

Table 1. Content of iron in the body compared with other metals.

Metals*	Content per 70-Kg man (mg)	Intake with diet per day (mg)
Fe	3.9 -5.0	12-15
Cu	0.12-0.15	2- 5
Zn	1.9 -2.0	10-15

*Mn, molybdenum, cobalt and chromium occur in the human body in an amount of 2 mg or less.

the lifetime of man (Tables 2 and 3). This was calculated assuming that 10% of iron ingested with food is absorbed (16, 17). Therefore, the amount of iron ingested must be tenfold the daily requirement. There is 6 mg of iron per 1000 Kcal in the average American diet. Therefore, iron intake from dietary sources is borderline for teenage girls and women, and may be inadequate for infants and pregnant women (18).

Iron Metabolism

Absorption. Absorption of iron occurs mainly in the small intestine. Absorption can occur along the entire length of the alimentary tract, but it is greatest in the duodenum and becomes progressively less distally (8). Two mechanisms exist for iron absorption across the mucosa of the upper intestine. These occur simultaneously; an active transport process with enzymatic or carrier characteristics

Table 2. Daily demand for iron in man at various ages.

	Absorbed iron requirement, mg/day
Infants	0.5-1.5
Children	0.4-1
Adolescents	1 -2
Normal men and nonmenstruating women	0.5-1
Menstruating women	0.7-2
Pregnant women	2 -4.8

Table 3. Iron requirements for pregnancy.

	Average mg	Range mg
External iron loss	170	150- 200
Expansion of red blood cell mass	450	200- 600
Fetal iron	270	200- 370
Iron in placenta and cord	90	30- 170
Blood loss at delivery	150	90- 130
Total requirement*	980	580-1340
Cost of pregnancy+	680	440-1050

*Blood loss at delivery not included.

+Expansion of red-cell mass not included.

and a first-order passive transport process, perhaps diffusion, that is operative primarily at doses of iron exceeding those in a normal diet (8, 11).

Iron is absorbed more easily in its ferrous form; ferrous iron passes into and through the mucosal cell directly into the blood stream, where it is immediately bound to transferrin. Small excesses of iron within the villous epithilial cells are oxidized to the ferric state, where they combine with the protein apoferritin to yield ferritin, which is eventually excreted in the feces incorporated in villous absorptive columnal epithelial cells. This "mucosal block" mechanism for handling excess iron can cope with only small excesses, and it is overwhelmed by large amounts of iron (13, 14).

To have a composite picture of iron absorption, Figure 1 shows ionic iron in the human intestine, there it adsorbs to specific receptors in the brush border of the mucosal cell. From these receptors, the iron is transferred to the cytoplasm of the mucosal cell by an active process involving energy. The absorbed iron appears to be present in the cytosol in small molecular weight form, possibly chelated to amino acids, and in equilibrium with iron-poor ferritin present there. On reaching the serosal surface of the cell, it becomes attached to transferrin for transport in the plasma. The serosal transfer mechanism probably also involves receptors in the cell membrane and may be

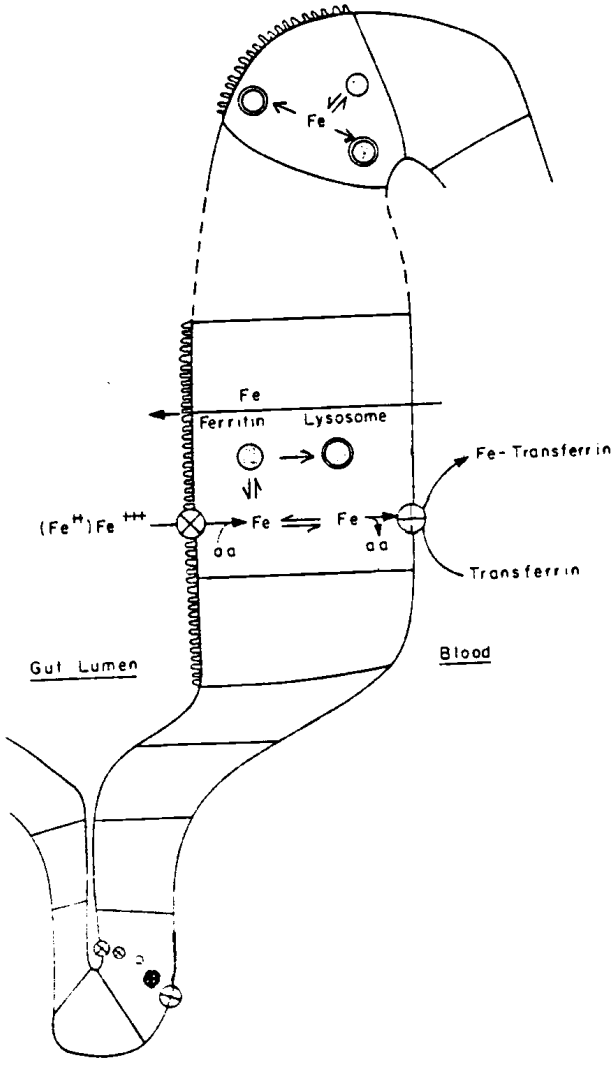

Figure 1. Composite picture of the mechanism and regulation of iron absorption in the intestinal mucosa (3).

independent of cell energy. Iron in the mucosal cell not transported to the plasma is retained in the cell, probably mostly as ferritin until it is sloughed off at the tip of the villus and thus returns to the lumen of the gut. The iron status and erythropoietic needs of the individual, as well as some other factors, regulate iron absorption, particularly at the level of serosal transfer. Finally, iron can enter the mucosal cell from the plasma,especially their mitochondria,and can pass into the lumen by active extrusion, notably in the lower part of the small intestine (3).

Transport. A glycoprotein bi-globulin called transferrin transports ferric iron after it has been absorbed to the bone marrow, where the iron is incorporated into hemoglobin (8).

Fate. The distribution of about 3.5 g of total body iron in the 70 kg male is shown in Figure 2. It exists exclusively complexed to protein (transferrin, ferritin) or in heme (hemoglobin, myoglobin, heme enzymes). Two-thirds is in hemoglobin, one-fourth is in the body's reserve stores as ferritin and hemosidein, 3% is in myoglobin, 0.5% is in heme enzymes, and a minute fraction is in transferrin (0.1% of body iron) (8).

Excretion. The body excretes only minimal amounts of iron. Normally this amounts to 0.5 to 1 mg daily. This excretion is in nails, hair, feces, and urine, mainly as

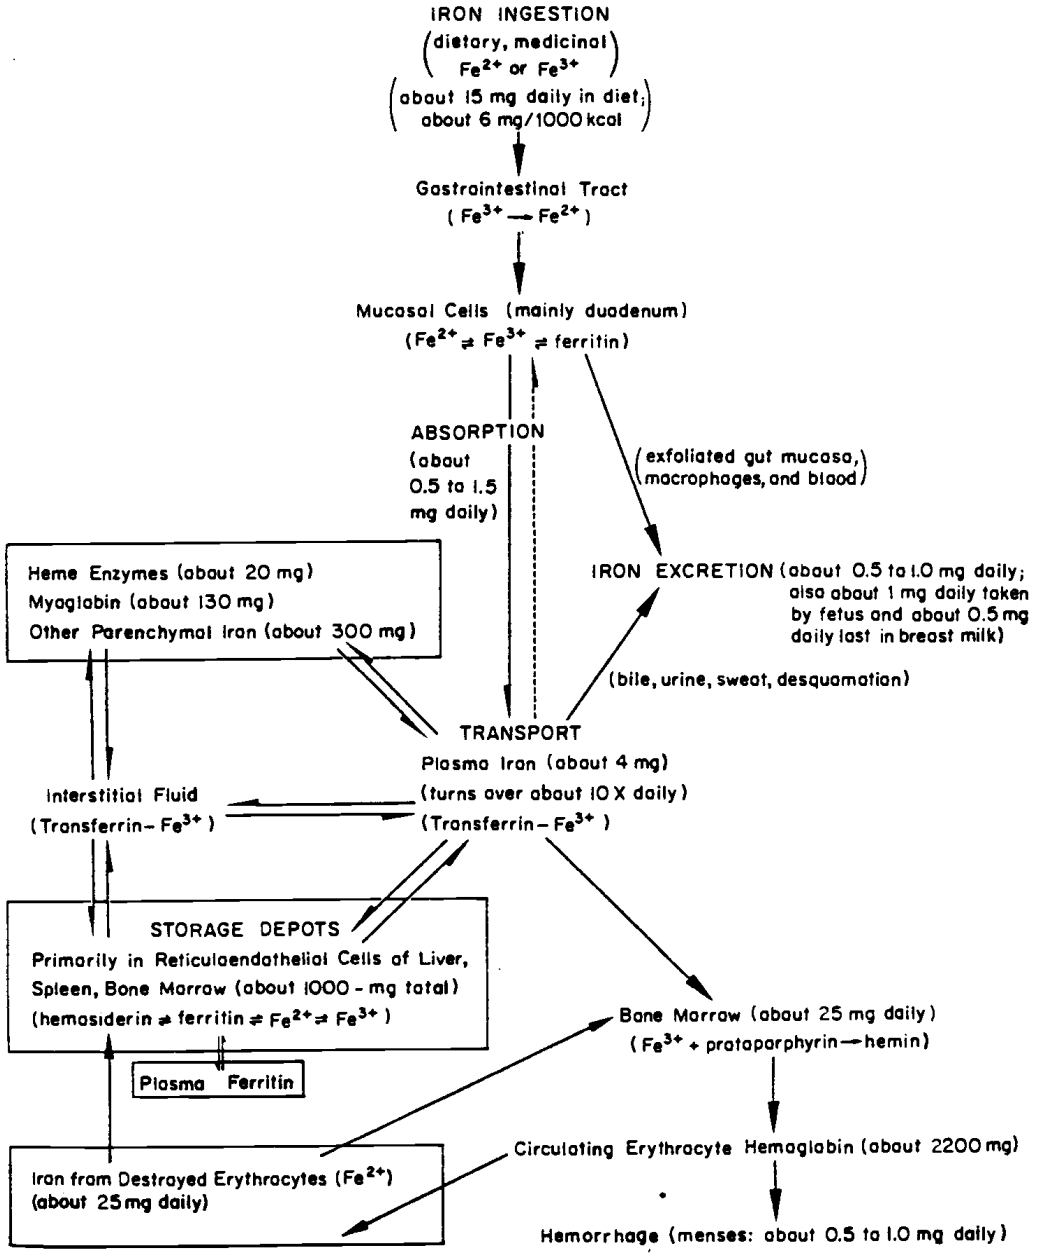

Figure 2. Normal absorption, metabolic pathways, and excretion of iron (8).

enzyme iron of exfoliated cells, but there are also trace doses in bile and cell-free sweat. The main excretory pathway is by way of epithilial cells sloughed from the skin and gastrointestinal tract, which carry out unneeded iron as ferritin (19, 20).

Adverse Reactions

Side Effects of Iron Therapy. Constipation occurs in about 10% of patients, diarrhea in about 5%, and nausea and epigastric pain in about 7% to 90% (8). This can be reduced by prescribing iron just after meals instead of between meals. When iron balance is restored to normal, therapy with iron should be stopped to avoid iron-overload hemosiderosis (19, 20).

Overdosage Toxicity. Iron poisoning is very rare in adults; it would be unlikely in adults with ingestion of doses of ferrous sulphate below 50 g. Acute poisoning in children can result from ingestion of doses in excess of 1 g (8). Signs and symptoms are those of gastrointestinal irritation and necrosis, often associated with nausea, vomiting and shock; they include pallor or cyanosis, lastitude, drowsiness, hematemesis, diarrhea of green and subsequently of tarry stools, and cardiovascular collapse. If death does not occur within 6 hours, there may be a transient period of apparent recovery followed by death in 12-48 hours. The corrosive injury to the stomach may result

in subsequent pyloric stenosis or severe gastric scarring (19). Hemochromatosis, i.e. the deposition of hemosiderin in the paranchyma of liver and other organs, has occurred in a few patients given iron for many years. It occurs idiopathetically and following multiple transfusion (7).

Treatment of Chronic Toxicity. Gastric lavage can be employed with a lavage solution that contains phosphate ion to combine with dissolved iron (8). Following lavage or induced emesis, a volume of phosphate solution appropriate to the size of the victim should be left in the stomach to decrease the solubility of iron remaining in the lumen. Specific treatment depends upon the use of chelating agents, which complex with metal ions, removing them from solution and incorporating them into less toxic chelate (7). Deferoxamine forms a nontoxic complex with iron with such avidity that it is able to extract iron from transferrin and ferritin. Figure 3 shows the chemical structure of ferroxamine (7).

Preparations and Dosages

Oral Preparations. Ferrous sulphate is usually the standard drug. Several preparations are available on the market (7). The most popular are shown in Table 4.

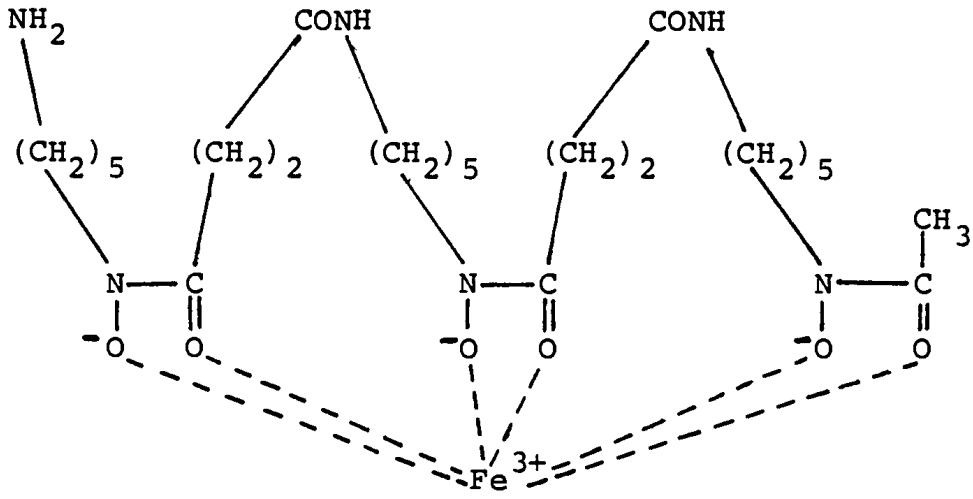

Figure 3. Chemical structure of ferroxamine. (Feroxamine without the chelated iron is deferoxamine-desferal.)(7)

Table 4. Iron for oral administration: dosages and preparations available (7).

	Iron content	Usual adult	Iron/ dose	Preparations available
Ferrous sulphate	20%	300 mg	60 mg	•Tablets (plain, coated or enteric-coated), 200, 300, and 325 mg •Controlled release tablets, 525 mg •Syrup or elixir, 125 mg/1 ml, 150mg/5 ml, and 220 mg/5 ml •Drops, 75 mg/0.6 ml
Ferrous sulphate, exsiccated (eg. Feosol)	30%	200 mg	60 mg	•Tablets and capsules, 200 mg; sustained release capsules, 150 mg
Ferrous gluconate (e.g., Fergen)	12%	300 mg	36 mg	•Tablets (plain, coated or enteric-coated), 325 mg •Elixir, 300 mg/5 ml
Ferrous fumarate (e.g., Toleron, Ircon)*	33%	200 mg	66 mg	•Tablets (plain, coated, or chewable), 200, 225, 250, and 325 mg •Suspension, 100 mg/5 ml
Ferroglycine sulfate (e.g. Ferronord)	16%	250 mg	40 mg	•Tablets (coated), 250 mg
Ferrocholinate (iron choline citrate; e.g., Ferrolip, Chel-Iron)	12%	330 mg	40 mg	•Tablets (coated), 330 and 360 mg •Syrup, 280 mg/1 ml and 417 mg/5 ml
Polysaccharide-iron complex (e.g., Niferex)			50 mg	•Tablets (coated), 50 mg elemental iron •Elixir, 100 mg elemental iron per 5 ml

Injectable Iron Preparations:

1. Iron-dextran injection (Imferon). The iron dextran complex contains 5% iron, i.e., 50 mg of iron per ml of solution.
2. Iron sorbit (Jectofer) is an iron-sorbiton complex comparable to iron-dextran complex. It also contains 50 mg of iron per ml.

Ways to Affect Iron Absorption

Extensive research has been done to study factors that affect iron absorption. It was found that iron is affected by the following:

Metal Precipitating Agents. Examples are: soluble carbonates, oxalates and phosphates which combine with metal ions to form insoluble complexes which are poorly absorbed. Also, the bicarbonates are effective in reducing iron uptake due to the formation of iron in a macromolecular form which cannot be absorbed (21).

Reducing Agents such as cysteine and hydroquinone increase the absorption of iron (11). The most famous example is ascorbic acid. The increase in iron absorption from a semisynthetic meal was directly proportional to the amount of ascorbic acid added over a range of 25 to 1000 mg (14). The ratio of iron absorption with/without ascorbic acid at these two extremes was 1.65 and 9.57 respectively. The reason behind this lies in the fact that

reducing agents keep iron in the reduced form (22-26).

Iron-Chelating Sugars such as fructose increase iron absorption (22). This was attributed to the fructose ability to form a stable complex with iron, thereby facilitating the transport of iron across the intestinal mucosa.

Composition of Diet influences the amount of iron absorbed. For example, iron fortification is necessary in Southeast Asian diets which contain a lot of rice (27-29). Alcohol and tea decrease iron absorption (30-32). Also, it was found that protein uptake is necessary for adequate iron absorption (33-35).

Deferoxamine. As mentioned before, it is used for iron toxicity (36). It binds strongly with iron forming a nontoxic complex which is eliminated from the body (Figure 3).

Ferrous iron is much more absorbed than ferric iron (37-39). In a medium with a pH value slightly above 3, solubility of ferric iron decreases because the sparingly soluble ferric hydroxides are formed (11). Ferric iron forms aggregates at pH 7.0 (40) and is much less soluble than ferrous iron at this pH (solubility products are approximately 10^{-36} for $Fe(OH)_3$ and 1.64×10^{-14} for $Fe(OH)_2$).

Amino Acids effect on the absorption of iron has been investigated by Kroe et al. (9, 10). The effect of

glutamine, aspargine, glutamic acid, serine, phenylalanine, proline, methionine, histidine and ethionine on iron absorption was tested. The activity of Fe-59 in the blood was found to be greater when the Fe-59 was administered orally with an amino acid than when it was administered alone (Figure 4). But, the results cannot be conclusive since phosphate was used as a buffer and it decreases iron absorption both *in vivo* and *in vitro* (11, 41). Peters *et al.* (41) studied the action of phosphate salts and phosphate-containing foods on iron absorption *in vivo* and compared the results to the interactions observed between iron and phosphate under conditions similar to those in the gastrointestinal tract. Phosphoproteins, calcium phosphates and phosphate salts were found to bind iron effectively and decrease dialysis across a membrane. Also, it was shown that phosphates act to accelerate the oxidation of ferrous iron to the ferric state and sequestering it as ferric phosphate which is precipitated (41).

Other Effects. Many other factors were studied that might affect iron absorption. The most famous are the decrease in absorption of iron due to calcium and phosphate salts, EDTA and antacids (42-44). Polychlorinated hydrocarbons stimulate iron absorption (45), while absorption of iron as supplements in infant cereal and infant formulas is low (46).

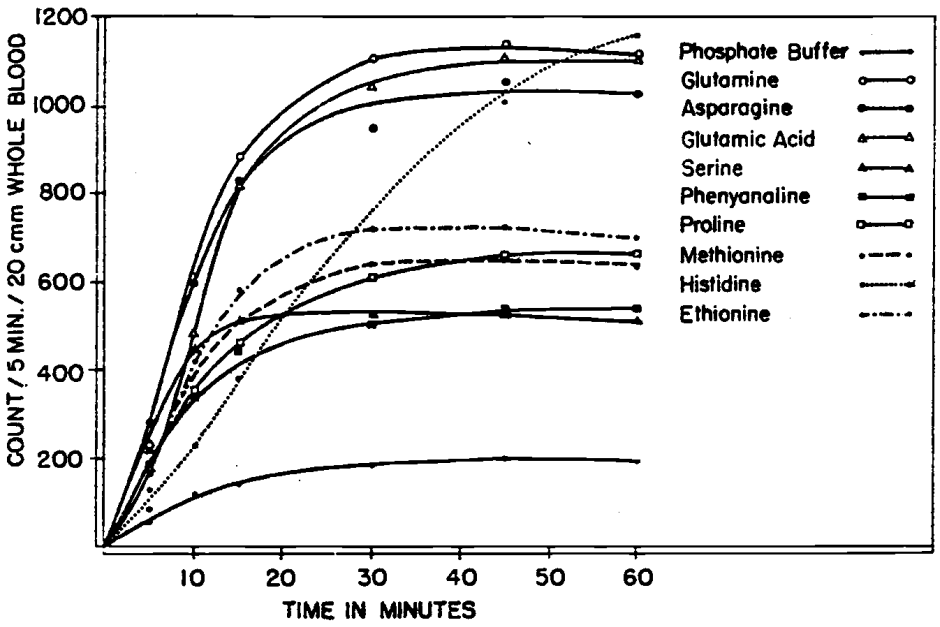

Figure 4. Fe^{59} activity curves in blood when various amino acids and phosphate buffers were administered (Figure 1 in reference (9)).

Stability Constants of Metal Complexes

During the past thirty years, much interest has been shown in obtaining dissociation constants for cations other than the hydrogen ion. The mass action equations are formally similar, but the results are customarily expressed as stability constants (47). It is convenient to write stability constants (which are the reciprocals of instability constants) as log K (and hence not as pK).

The Nature of Chelation

Any substance which can bind a proton can bind a metallic cation instead. At high proton concentrations, the proton will be greatly preferred, at low proton concentrations, the metallic cation may be preferred if it is present in great excess, or better, if a new ring can be formed by two groups in the molecule which simultaneously bind the metal. This simultaneous binding is termed chelation, and confers stability on the complex. If the pH is allowed to rise too high, the free metal cations may be precipitated as the hydroxide or as self-complexes (48).

In general, chelation through oxygen or nitrogen atoms takes place only when 5- or 6-membered rings can be formed, and of these, the 5-membered rings are more stable. In the presence of excess ligand, 2:1 complexes can be formed (47, 49). It is now agreed that the equilibrium

between a complex forming agent and an ion is usually thermodynamically reversible: it occurs instantly and without appreciable energy of activation. Hence these equilibria are correctly represented by mass action equations (47).

Designing a Chelate Drug

The medical importance of chelating agents hinges on the fact that metals play many critical roles in the life of living organisms. In the human body metabolism depends not only on sodium, potassium, magnesium and calcium but also to a considerable degree on trace amounts of iron cobalt, copper, zinc, manganese and molybdenum. On the other hand, certain other metals, even in minuscule amounts, are highly toxic to the body. It is apparent, therefore, that chelate drugs with appropriate properties could play several different therapeutic roles. Various chelating agents might be designed (1) to seek out toxic metals and bind them in compounds that will be excreted, (2) to deliver essential trace metals to tissues or substances that require them, and (3) to inactivate bacteria and viruses by depriving them of metals they need for their metabolism or by delivering metals to them that are harmful. All three of these hopes have been realized (17).

Obviously, in the design of chelate drugs for specific purposes, everything depends on the relative affinity of the chelating drug for the given metal. To be effective in removing a metal, the drug must seize and hold it more strongly than any biological substance that might be available to form a compound with the metal. To deliver a metal to the cells, on the other hand, the grip of the carrier drug must be comparatively loose; that is, the drug's affinity for the metal must be less than that of the substance to which the metal is to be surrendered. Hence an important part of the research on chelating agents has been the development of ways to measure the affinities between various substances and metal ions (17).

Stability Constants

Stability constants are determined in order to assess the affinity between ligands and metals, a property which varies between wide limits. For the 1:1 complex of glycine and ferrous ion, K_1 (the first stability constant), is given by equation (48)

$$K_1 = \frac{[H_2N \cdot CH_2 \cdot CO_2 \cdot Fe^+]}{[Fe^{+2}]\,[H_2N \cdot CH_2 \cdot CO_2^-]}$$

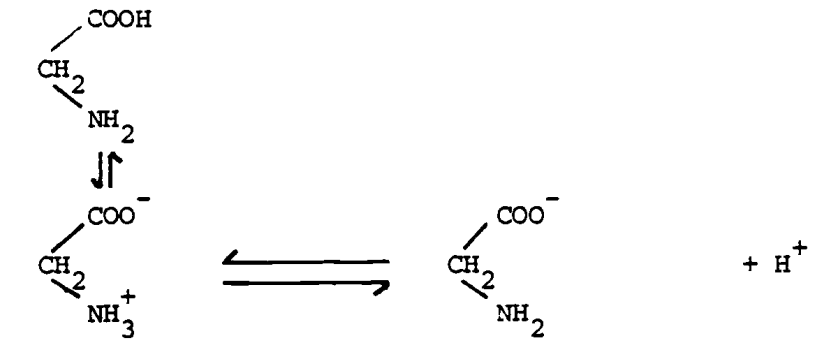
and for the 2:1-complex (48)

$$K_2 = \frac{[H_2N \cdot CH_2 \cdot CO_2 \cdot Fe \cdot O_2C \cdot CH_2 \cdot NH_2]}{[H_2N \cdot CH_2 \cdot CO_2 \cdot Fe^+]\,[H_2N \cdot CH_2 \cdot CO_2^-]}$$

In each case the formed complex is in the numerator, and the substances which form it are in the denominator. For our purposes, the product of the constants, i.e., the overall stability constant "K_s" is required. $K_s = K_1K_2$ (47-50).

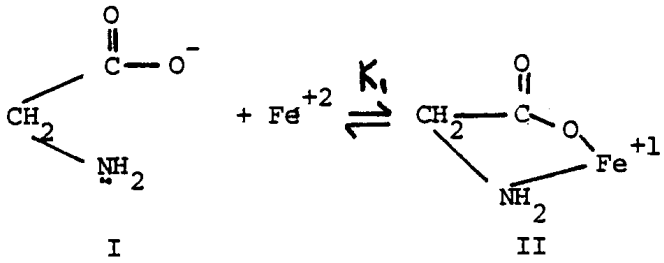
Amino Acid Chelation with Iron

To explain chelation of amino acid with iron, glycine will be used as an example. When amino acid is in solution a zwitterion and a free complex forming species (I) are formed. The free complex forming agent is the one which is capable of chelation. Two free complex forming agents bind and chelate with one iron forming chelate (III) (47-51).



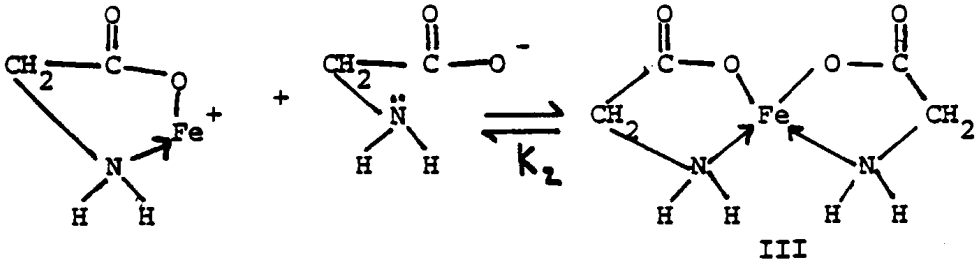
Zwitter iron

I Free complex forming species



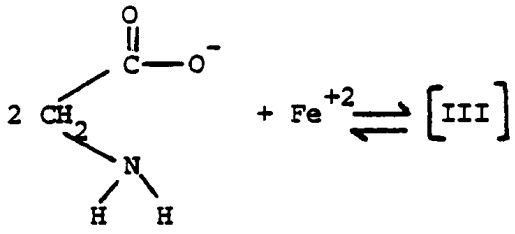
I

II



III

$$K_1 = \frac{[II]}{[I][Fe^{+2}]} \quad , \quad K_2 = \frac{[III]}{[I][II]}$$



$$2[I] + Fe^{+2} \rightleftharpoons [III] \qquad \text{TOTAL REACTION}$$

$$\therefore K_s = \frac{[III]}{[Fe^{+2}][I]^2} = \frac{K_2[II][I]}{[Fe^{+2}][I]^2} = K_1K_2$$

$$\therefore K_s = K_1K_2$$

Neutron Activation Analysis

Introduction

By bombardment with neutrons (charged particles and high-energy photons) stable atoms can be transformed into radioactive isotopes. By measuring the radiation emitted from a bombarded sample, the presence of one or more elements of particular interest in the sample often can be determined quantitatively. This approach to detection of trace

elements and analysis of the chemical composition of a sample is referred to as activation analysis. Activation analysis is now being used widely in a variety of analytical problems where high sensitivity is required. The greater part of this work is being performed with thermal neutrons. The reason for this is the general availability of nuclear reactors and the large cross section of many nuclides for thermal neutron capture. Sensitivity of 10^{-9} grams is not unusual (52-54).

Radiation Sources for Activation Analysis

Activation analysis of a sample may be performed with any type of radiation which transforms stable atoms into radioactive isotopes. For example, slow and fast neutrons, protons, deuterons[2], triton,[3], α particles, and high energy x- and γ-rays have been employed for activation analysis. Most often samples are activated with neutrons, especially slow (thermal) neutrons (53).

Most elements with Z[4] above 10 exhibit reasonable cross sections for activation by thermal neutrons. Usually, the activation is achieved by an (n,γ) reaction, and the product nucleus is a radioactive isotope of the target

---

[2]Deuteron = nucleus of deuterium.

[3]Triton - nucleus of tritium.

[4]Z = atomic number

element. The four major compounds (H, C, N and O) of biologic tissue have atomic numbers less than 10 and are activated only rarely by thermal neutrons. Consequently, thermal neutrons are useful for analysis of trace elements in biologic tissue, because the higher Z trace elements can be activated and detected without interference from activated products of the four low-Z elements which constitute the major portion (96%) of biologic tissue (52, 55, 56).

Nuclear Reactors

In a nuclear reactor, a fissionable nuclear fuel such as ^{235}U is placed in a defined geometry within the reactor core. Fast-moving neutrons released as the ^{235}U nuclei fission are slowed to thermal energy ($\sim$0.025 eV) by a low-Z moderator such as water, heavy water or beryllium. The slowly moving neutrons are absorbed by additional ^{235}U and a chain reaction is maintained. The rate of absorption of slow neutrons by fissionable nuclei determines the fission rate for the reactor, and is controlled by placing inert neutron absorbers in the reactor core. Typical neutron absorbers, usually termed control rods, include boron and cadmium. Heat generated in the reactor core is removed by a coolant such as water or one of a variety of gases or liquid metals (53, 54).

Activation of Prepared Tablets

After preparing the iron tablets, there was the problem of testing them *in vivo* in rabbits. A new method which involves neutron activation analysis was designed. Tablets of two types were activated. The first type was iron tablets without glycine (control), and the second type was iron with glycine. The advantages of this method are numerous. To include some: it is safe, economical, fast, practical in elemental analysis, and last but not least, it is not destructive to the sample (57).

After having a computer search on the literature since 1960, no reports of activation were found of any type of tablets in order to test them *in vivo*.

Equation for Neutron Activation

Activation analysis equation:

$$A = N\phi\sigma(1 - e^{-\lambda T})e^{-\lambda t}$$

where A = activity at end of irradiation (dis/sec)

N = number of atoms

ϕ = flux (neutrons/cm^2-sec)

σ = cross section (cm^2/atom)

λ = decay constant (sec^{-1})

T = length of irradiation (sec)

t = time elapsed between activation and measurement

The induced activity depends upon the neutron flux density, the cross sections for activation of the target atoms, the irradiation time, and the number of target atoms in the sample. The activity at the time of measurement of the radiation depends also upon the half-lives of the isotopes of interest and the time elapsed between activation and measurements (53, 54). Activation analysis is subject to a variety of errors. These include errors due to flux gradients, self shielding, and interfering nuclear reactions (53).

III. EXPERIMENTAL PROCEDURE

Determination of Stability Constant of Ten Amino Acid Complexes with Iron

Ten amino acids: glycine, l.-proline, d.l.-tryptophan, l.-asparagine, d.l.-alanine, d.l.-phenylalanine, d.-serine, d.l.-methionine, d.l.-leucine and l.-isoleucine were obtained from J.T. Baker.

The method of determining the stability constant is a standard method and was used for determining all types of chelations between amino acids and metals (47-50).

The above amino acids were all dried for one hour before weighing. Then each amino acid (50 ml of 0.01 M - aqueous solution) was titrated with 0.1 N KOH, first in the absence of metals and then in the presence of one equivalent of the ferrous salt (0.005 M). Thus the molar ratio of the complex forming agent to metal was 2:1 for all bivalent ions. The amount of alkali used in each titration was 5 ml (i.e. the equivalent of the amount of complex-forming agent) and this was added in ten equal portions of 0.5 ml.

The experiment was done in a water bath that was at 37°C and the amino acid solution was stirred continuously by N_2 to maintain an inert atmosphere above the solutions. Boiled water was used since air must be removed from the

system to avoid change in base concentration. The pH was recorded after each addition (47-50).

Preparation of the Buffer

A potassium hydrogen phthalate, sodium hydroxide buffer solution was prepared with a final pH of 6.0. Such a buffer contains 50 ml of 0.1 M KHP (potassium hydrogen phthalate) and 43.7 ml of 0.1 M NaOH diluted to 100 ml (58).

Procedure Involving Rats

Solutions of iron complexed with each of the ten amino acids, as well as the control solution alone, were administered orally to groups of six rats. The amino acids were glycine, l.-proline, d.l. trypotphan, l.-asparagine, d.l.-alanine, d.l.-phenylalanine, serine, d.l.-methionine, d.l.-leucine, l. isoleucine. All these amino acids, except asparagine, have one amine and one carboxyl group. Thus, two molecules of each amino acid will complex with one atom of iron.

Male albino rats, weighing 250-270 gm each, were used. Rats were fasted 24 hours before the start of the experiment to prevent complexing agents present as food constituents in the intestinal lumen which may affect iron absorption (9). Iron in the form of ferrous sulphate was used in all experiments. Test solutions were prepared by

adding an amino acid and $Fe^{59}SO_4$ to aliquots of KHP-NaOH buffer so that the resulting Fe-59 activity was 10 μc/ml. The amino acid concentration was 0.4 M, ascorbic acid was 0.5 M and ferrous sulphate 0.2 M. A control solution was prepared using the same procedure, but not containing any amino acid.

An intubation tube[5] was put in the rat's mouth and 1 ml of test or control solution was delivered into his stomach. The tube was then removed and the rat was kept under anesthesia (ether) during the whole experiment.

At time periods of 5, 10, 15, 20, 30, 45, 60, 90, 120, 150, 180, 210 and 240 minutes, after administration of the solution, 20 lambda of blood samples were collected from the toes of the rat using capillary tubes. The capillary tubes were placed into counting vials. Each sample was counted for 10 minutes in a solid scintillation counter chamber.[6]

At the end of the four hours, the animals were sacrificed by ether and liver, kidney, heart, brain and muscle samples were taken from the animals, weighed and then counted for ten minutes.

[6]Tracer Northern TN-1705 MCA 40 cc NaI(Tl) detector.

Production of Tablets

Direct compression was used to produce tablets.[7] Two types of tablets were prepared. The first type has glycine and ferrous chloride. The second type, the control one, does not have glycine.

Type 1 (average weight of each tablet was 0.4152 gm)

Formula for 1 tablet of Type 1 -

Dipac[8]	296.6189 mg	71.44%
Mg Stearate	29.6452 mg	7.14%
Glycine	39.5270 mg	9.52%
Ferrous chloride	49.4088 mg	11.90%

Type 2 (average weight of each tablet was 0.4053 gm)

Formula for 1 tablet of Type 2 -

Dipac[8]	328.1309 mg	80.96%
Mg Stearate	28.9384 mg	7.14%
Ferrous chloride	48.2307 mg	11.90%

Disintegration tests were done for both types using the Vanderkamp USP tablet and disintegration tester (59).

Activation of Tablets

Tablets were put in small scintillation bags.[9] Each

bag was sealed by heat and then put in a polyvial.[10] Then the polyvials were sealed by heat. All these samples were put in the OSU TRIGA reactor in the Lazy Susan and activated with a neutron flux of $3x10^{12}$ neutrons/cm^2/sec. The irradiation time was four hours.

Procedure Involving Rabbits

The iron-glycine activated tablets, as well as the control activated tablets, were each tested on groups of four rabbits. Female rabbits were used, weighing 2.0-3.0 kg each. Each rabbit had his ears shaved using an electric shaver and Nair ^{R} ointment. Then, the rabbit was put in a rabbit restrainer leaving his head out, and was given four tablets that had a total activity of 1.0824 µcurie.

At time periods of 5, 10, 15, 20, 30, 45, 60, 90, 120, 150, 180, 210, 240 minutes after administration, 100 lambda blood samples were collected from the rabbit's ears using capillary tubes. Bleeding was initiated by pricking the vein of the rabbits' ear with a 20 gauge needle. Procaine was used as a local anaesthetic. These samples were placed into counting vials. Each sample was counted for 4000 seconds in a solid scintillation counter chamber.

At the end of four hours, the animals were sacrificed by ether and liver, kidney, muscle and heart samples were

---

taken from the animals, weighed and then counted in the same manner as before.

IV. RESULTS AND DISCUSSION

Figures 5 to 11 summarize the results of this project. Tables 5 to 26 show iron concentration in blood and different tissues foolowing the oral administration of each amino acid-iron complex. The iron concentration presented was calculated from the iron activity and does not include iron present before the administration. All data were analyzed using the National Institute of Health Computer Prophet System. Results show that there were greater amounts of iron absorbed when iron was administered with an amino acid than when it was administered with buffer alone.

For all these amino acid-iron complexes, the amount of iron in the blood versus time was found to fit a polynomial of degree 3 (r^2= 0.9857- 0.991). The empirical equation for all iron concentration curves is therfore:

$$Y= B_o + B_1T + B_2T^2 + B_3T^3$$

The initial rate of absoption is the tangent to the iron concentration curve at time zero and is equal to B_1 after differentiating dy/dt.

The effects of different amino acids on iron absorption from time zero to four hours were compared with the control by comparing the area under the curve for each amino acid-iron complex from time zero to four hours. When integrating the above equation over the experimental period of four hours,

the area under the curve (AUC 0-240 min) for each amino acid and amino acid-iron complex can be obtained as:

$$\int_0^{240} y\,dt = \int_0^{240} (B_0 + B_1T + B_2T^2 + B_3T^3)\,dt$$

$$= 240\ B_0 + 28800\ B_1 + 4608 \times 10^3\ B_2$$

$$+ 82944 \times 10^4\ B_3$$

It is evident from these experiments (Table 27 and Figure 5), that iron appears more quickly and in greater amounts in blood if it is administered with an amino acid than alone. The amount of circulating iron is a reflection of four factors: (1) the amount and rate of absorption, (2) the amount and rate of deposition in the tissues, (3) the release of iron from the tissues into the circulation, and (4) loss of iron from the body. Also, it can be seen from the curves (Figure 5) that the quantity of iron appearing in the blood was not identical for the different amino acids.

The amino acids could be grouped into three categories on the basis of increase of iron absorption over the control. Category I consists of asparagine and glycine which increase the area under the iron concentration curve by 265.22% and 224.52% respectively (Figure 5); Category II consists of serine where the increase was 114.29% (Figure 5); Category III consists of alanine, proline, isoleucine,

leucine, methionine, tryptophan and phenyl alanine where the increase was 64.46%, 44.89%, 34.82%, 29.79%, 24.66%, 20.89% and 24.28% respectively (Figure 5). These curves are enlarged in Appendix B.

The initial rate of absorption was in the following order starting with the amino acid that increased the initial rate of absorption most: glycine, serine, leucine, methionine, isoleucine, tryptophan, alanine, asparagine, phenyl alanine and proline (Table 27).

At the end of four hours, the rats were sacrificed and tissue samples collected for counting. The uptake of iron by the selected tissues is shown in Figures 6 to 11. The concentration of iron in the tissues of animals receiving amino acid-iron complexes was consistent with iron levels in the blood. Iron concentration was highest in the tissues of animals receiving asparagine-iron and glycine-iron complexes, while it was low in the tissues of animals receiving the other amino acid-iron complexes. The fact that the tissue iron content at the end of the experiment was significantly higher in the animals receiving amino acid-iron complexes indicates that the elevated blood-iron activity in these animals is a reflection of increased absorption from the gastrointestinal tract.

In the tissues, iron was found mostly in the liver (Figure 6). Lesser amounts were found in the heart and

kidney (Figures 7 and 8), and very small amounts in the muscle and brain (Figures 9 and 10). This was consistent for the control experiments as well as all ten amino acid-iron complexes. The stores of iron are mainly in reticule endothelial cells, and thus are found in organs rich in such cells, especially liver. The amount of storage iron varies with the sources and also with demands made upon it for hemoglobin formation (8).

The amount of iron in the gut was determined after administration of phenylalanine-iron and methionine-iron complexes where the increase in iron absorption was lowest and asparagine-iron complex where it was highest. The amount of iron in the gut was much higher in the case of phenylalanine-iron and methionine-iron complex (Figure 11). This too, is an indication that the elevated blood-iron activity in the animals is a reflection of increased absorption from the gastrointestinal tract.

Hober, in 1903, suggested that protein breakdown products participated in the absorption of iron (59). Also, the effect of proteins on iron absorption has been described as either positive or negative. Egg protein retards the absorption of iron (60, 61); it is not known whether the effect is related to its content of conalbumin. Conalbumin forms a stable complex with iron that in vitro drastically reduces the transfer of iron in jejenul segments of normal and anemic rats (11). Egg yolk also

contains phosphoproteins that form stable complexes with iron (41, 62).

An absorption-enhancing action of proteins has been reported repeatedly (9-11). This effect may account for the high fraction of iron in meat that is absorbed and for the enhancement of iron absorption from vegetable food by meat ingestion (63, 64). The differential effect of proteins on the absorption of iron probably can be attributed to the degree of proteolysis in different experiments (11).

It has been shown that amino acids in general are effective chelating agents (9-11) and that certain of these will affect the absorption of iron. It was suggested that amino acids facilitate absorption by chelating iron in the lumen of the gut, acting as vehicles for its absorption (9, 65). In 1977, Linder and Munro (3) suggested that iron-amino acid chelate goes into the muscosal cells. On reaching the serosal surface of the cell the amino acid leaves the iron and iron gets attached to transferrin for transport in plasma (Figure 1).

Theoretically, there are two types of iron complexes or chelates with different effects on the availability for iron absorption: 1) iron complexes or chelates of high effective stability that essentially do not release their metal for absorption; 2) iron complexes or chelates of lesser effective stability which do release iron for absorption. Various factors determine the degree of

metabolic utilization of iron, e.g. distribution in the organism, excretion, and, especially, ability of the organism to split the complexes and liberate the iron. As was mentioned before, EDTA and Deferroxamine (Figure 3) have high affinity for iron and thereby a very stable complex is formed. The organism cannot split such complexes and liberate the iron (7, 45). There are acceptor sites on the surface or within the mucosal cells that compete for iron with the ligands in the gut lumen. This is an important factor for understanding the role that iron competes with different stability complexes play by making iron available for absorption (17).

In the present study, no correlation was found between the stability constants for the amino acid-iron complexes tested and area under the iron concentration curve or with the initial rate of absorption (Figures 12 and 13). Thus, the stability constants are not predictive in the present study, because when the chelating drug is introduced into a living organism many interfering factors come into play. Substances in the organism will compete with the drug for the metal in which we are interested; conversely, various ions in the organism will compete with this ion for combination with the chelator. A famous example of this situation is the affinity between EDTA and mercury in the test tube is strong, in the body it is so weakened by interfering factors that EDTA is ineffective against

mercury poisoning. On the other hand, EDTA is quite effective in eliminating zinc from the body, because of the relative weakness of competing or interfering factors even though EDTA's absolute affinity for zinc is about a million times less than its affinity for mercury (12).

Effect of reducing power of food on iron absorption has been demonstrated repeatedly (19, 20, 21). Reduction of ferric to ferrous iron is favored by the reducing agents. The importance of reducing agents lies in the fact that iron is absorbed mainly in the divalent form (37-39). Also, it is now known that labilization of stable ferric complexes occur by reducing agents. This helps liberation of iron from ferritin (66,67). The most important reducing agent used is ascorbic acid. Ascorbic acid is added to many iron preparations in order to increase iron absorption. Tables 28, 29 and Figures 14, 15 show iron concentration in blood and different tissues following the oral administration of iron and ascorbic acid. It was found that the area under the iron concentration curves (time zero to four hours) increased by 31.59% (Figure 14). This occurred although ascorbic acid was given in much higher concentrations than ferrous sulphate (5:2), while the amino acid concentration compared to ferrous sulphate was (2:1).

Table 30 shows iron concentration in blood following oral administration of iron-glycine in the absence of

buffer. Figure 16 compares blood iron concentration of iron-glycine in the absence and presence of buffer. The area under the iron concentration curve of glycine-iron complex (time 0-4 hours) in the presence of buffer is 11.4% more than AUC (time 0-4 hours) of glycine-iron complex in the presence of buffer. The reason behind this lies in the fact that in the presence of buffer, the metallic cation binds better (48).

It was found that asparagine was much more expensive than glycine. Glycine costs $22.02/kg while asparagine was $114.84/kg[11]. So, glycine was used in the preparation of tablets. Also ferrous chloride was used rather than ferrous sulphate when preparing the tablets. The reason is because the tablets were to be activated, and the less radioactive the tablets are, the more it is convenient for handling them. S-35, with a half life of 88 days, is produced when activating ferrous sulphate. Cl-38, with a half-life of 37.3 minutes, is produced when ferrous chloride is activated (68). So, Cl-38 decays very quickly after the end of bombardment and is very easy to handle.

After the tablets were prepared using direct compression, disintegration tests were conducted. The Vanderkamp tablet disintegration apparatus was used. Eighteen tablets of each type were tested. Seventeen glycine-iron

---

[11]J. T. Baker prices.

tablets disintegrated within 18 minutes, while the 18th tablet disintegrated in 23 minutes. On the other hand, 16 control tablets disintegrated within 15 minutes, while the other two were within 19 minutes. The reason for this slow disintegration is that the tablets were harder than usual (15 kg/in^2).

A new technique using neutron activation analysis was introduced to test the prepared tablets *in vivo*. Glycine-iron and control tablets that didn't have amino acid, were activated for four hours in the Lazy Susan in the OSU TRIGA reactor. The activated tablets were administered to groups of four rabbits. Blood and tissue samples were collected in the same manner as that for rats. After having a computer search on the literature since 1960, no reports of activation were found of any type of tablets in order to test them *in vivo*. Neutron activation analysis is very useful in analytical problems where high sensitivity is required. Sensitivity can reach 10^{-9} gm. It is safe, economical, fast, practical in elemental analysis and non-destructive (57). Also, as was discussed in Chapter I, thermal neutrons do not activate isotopes with atomic numbers less than 10. Therefore, carbon, hydrogen, oxygen and nitrogen, which have atomic numbers less than 10 are not activated.

Tables 31-34 and Figures 17 and 18 show iron concentration in blood and different tissues following the oral

administration of glycine-iron and control activated tablets to rabbits. It is evident from these experiments that involved rabbits, that iron appears more quickly and in greater amount in blood when the tablets had glycine. The area under the iron concentration curve for the time during which data was collected increased by 67% when the tablets had glycine (Figure 17).

The amount of iron in the different tissues was also consistent with iron levels in the blood. Iron concentration was highest in the tissues of the rabbits that received the glycine-iron tablets (Figure 18).

V. CONCLUSIONS

1. The effect of ten amino acids on iron absorption was studied. Area under the iron concentration curves (time 0-240 min) for all amino acid iron complexes increased over the AUC (time 0-240 min) of the control. The increase in the area under the curve was most notable in asparagine and glycine where the increase was 265.22% and 224.52% respectively. The concentration of iron in the tissues of animals receiving amino acid-iron complexes was consistent with iron levels in the blood. Iron concentration was highest in the tissues of animals receiving asparagine-iron and glycine-iron complexes, while it was lower in the tissues of animals receiving the other amino acid-iron complexes.
2. No correlation was found between stability constants of each amino acid-iron complex and initial rate of absorption or area under the iron concentration curve (0-4 hr). This suggests that there are substances in the animals that compete with the amino acid ligands for iron. Conversely, various ions in the animal might compete with iron for combination with the amino acids.
3. It was found that amino acids increase iron absorption much more than ascorbic acid. Asparagine and glycine increase the area under the iron concentration curve (time zero to four hours) by 265.22% and 224.52%, while

in the case of ascorbic acid the AUC (time 0-4 hours) increases by only 31.59%.

4. A new technique using neutron activation analysis was introduced to test tablets having metals in vivo. This method is highly sensitive, safe, economical, fast, practical in elemental analysis and non-destructive.
5. A new tablet formulation containing iron was prepared that was tested after activation on groups of rabbits. Results showed that iron absorption was more when the tablets had glycine than control tablets without glycine.

APPENDIX B

Computer Predicted Figures for Each Amino Acid-Iron Complex

These figures include (a) blood iron concentration, and (b) iron concentration in organs following oral administration of amino acid-iron complexes.

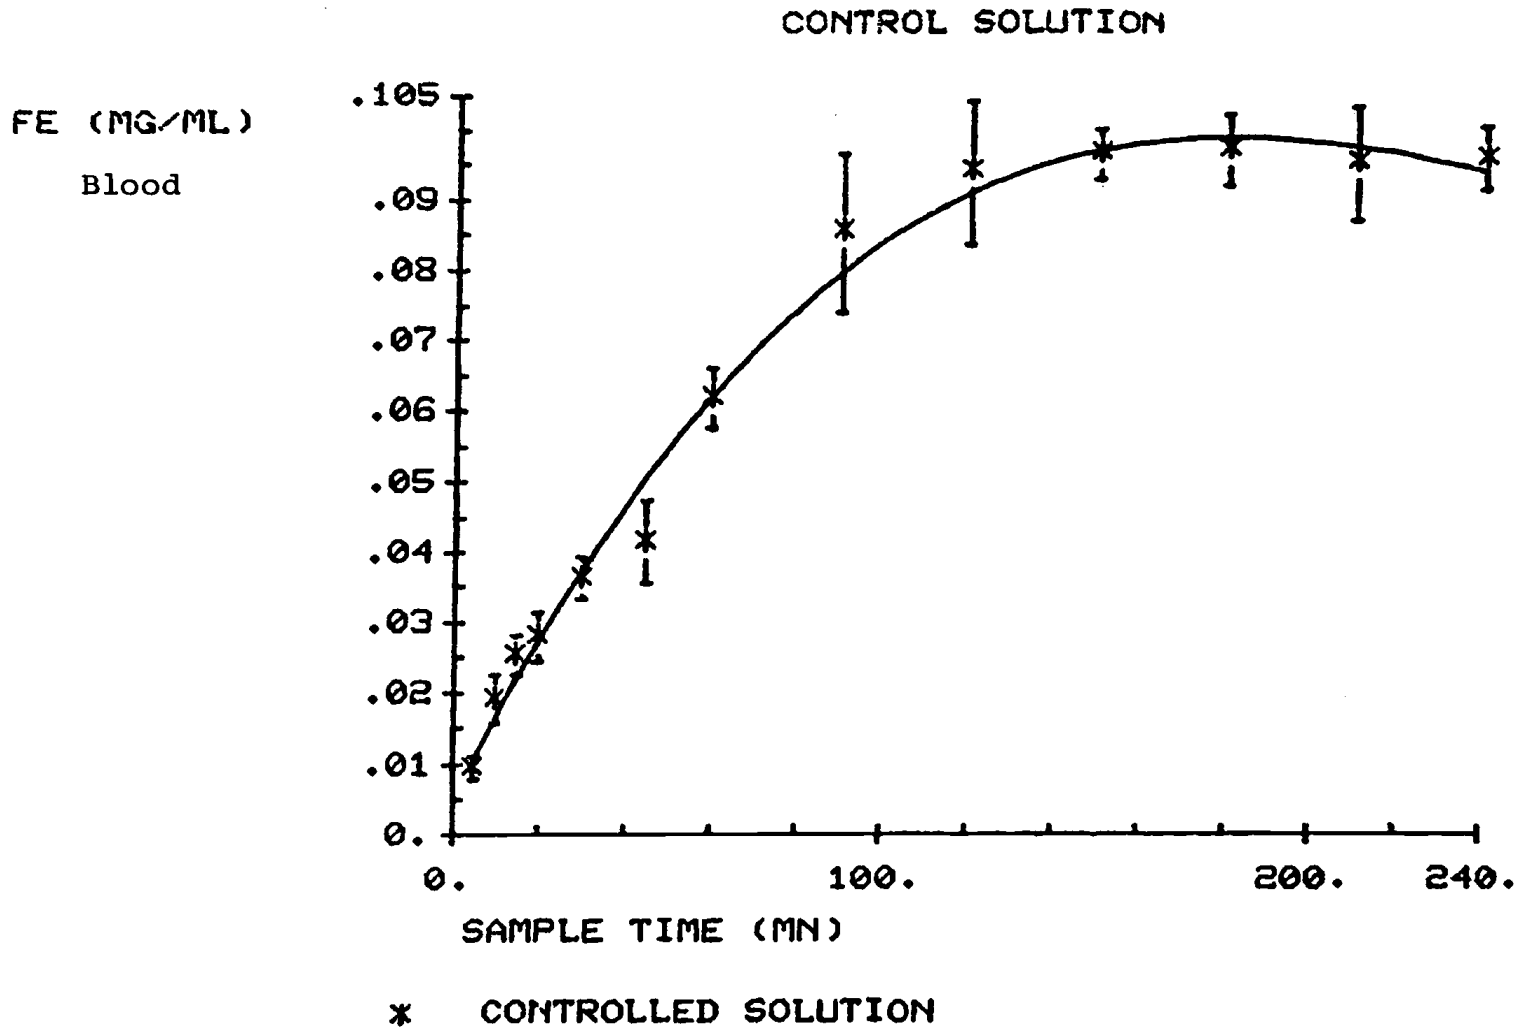

Figure B-1. Blood iron concentration following oral administration of 0.2 M ferrous sulphate (55.6 mg/ml) given as control

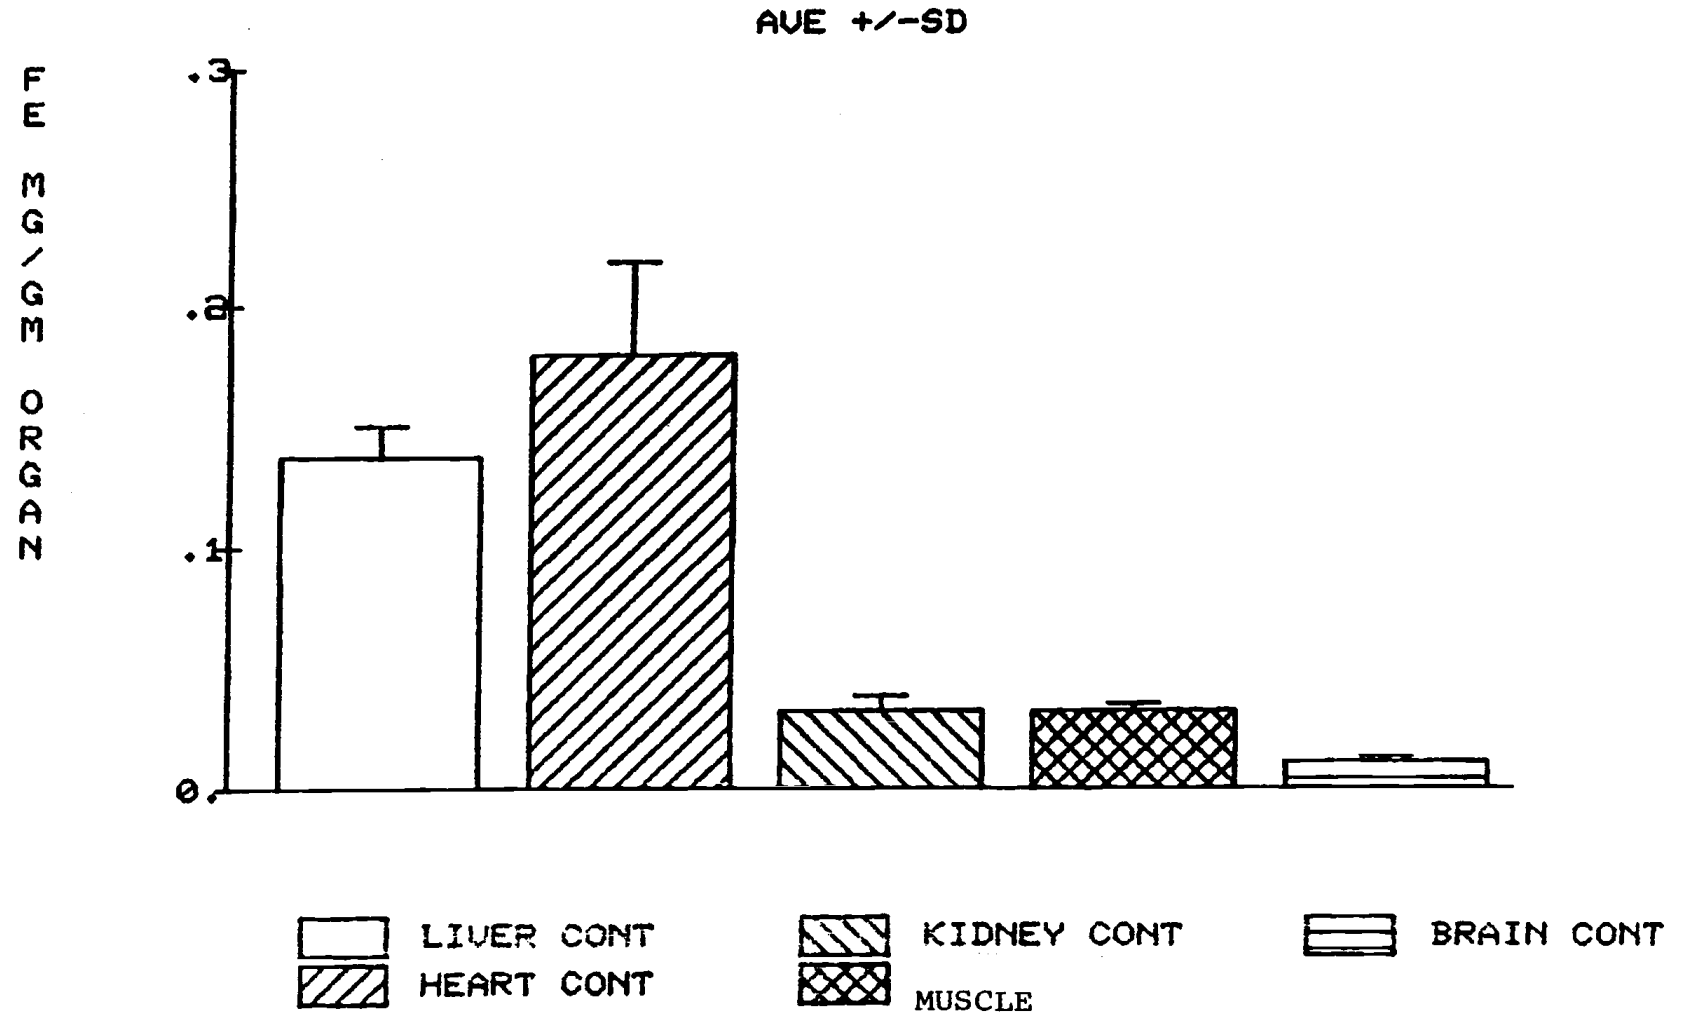

Figure B-2. Iron concentration in organs four hours after the oral administration of 0.2 M ferrous sulphate (55.6 mg/ml) given as control.

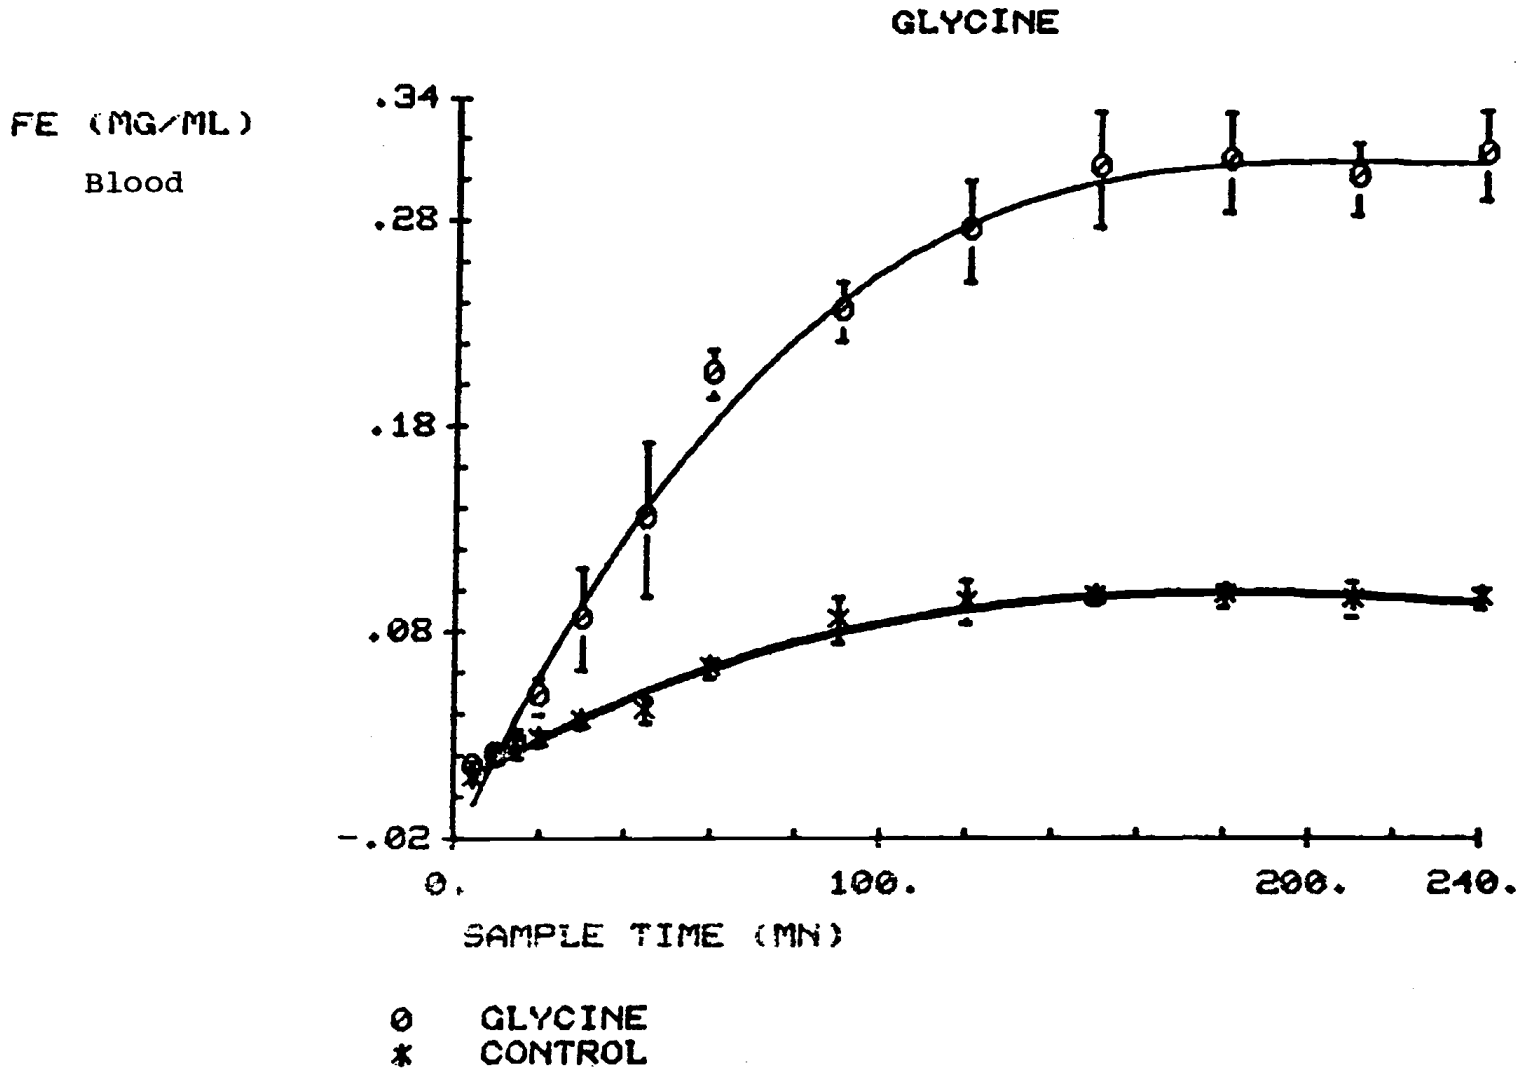

Figure B-3. Comparison of blood iron concentration when 0.2 M ferrous sulphate (55.6 mg/ml) given as (1) control and (2) with 0.4 M glycine (30.0 mg/ml).

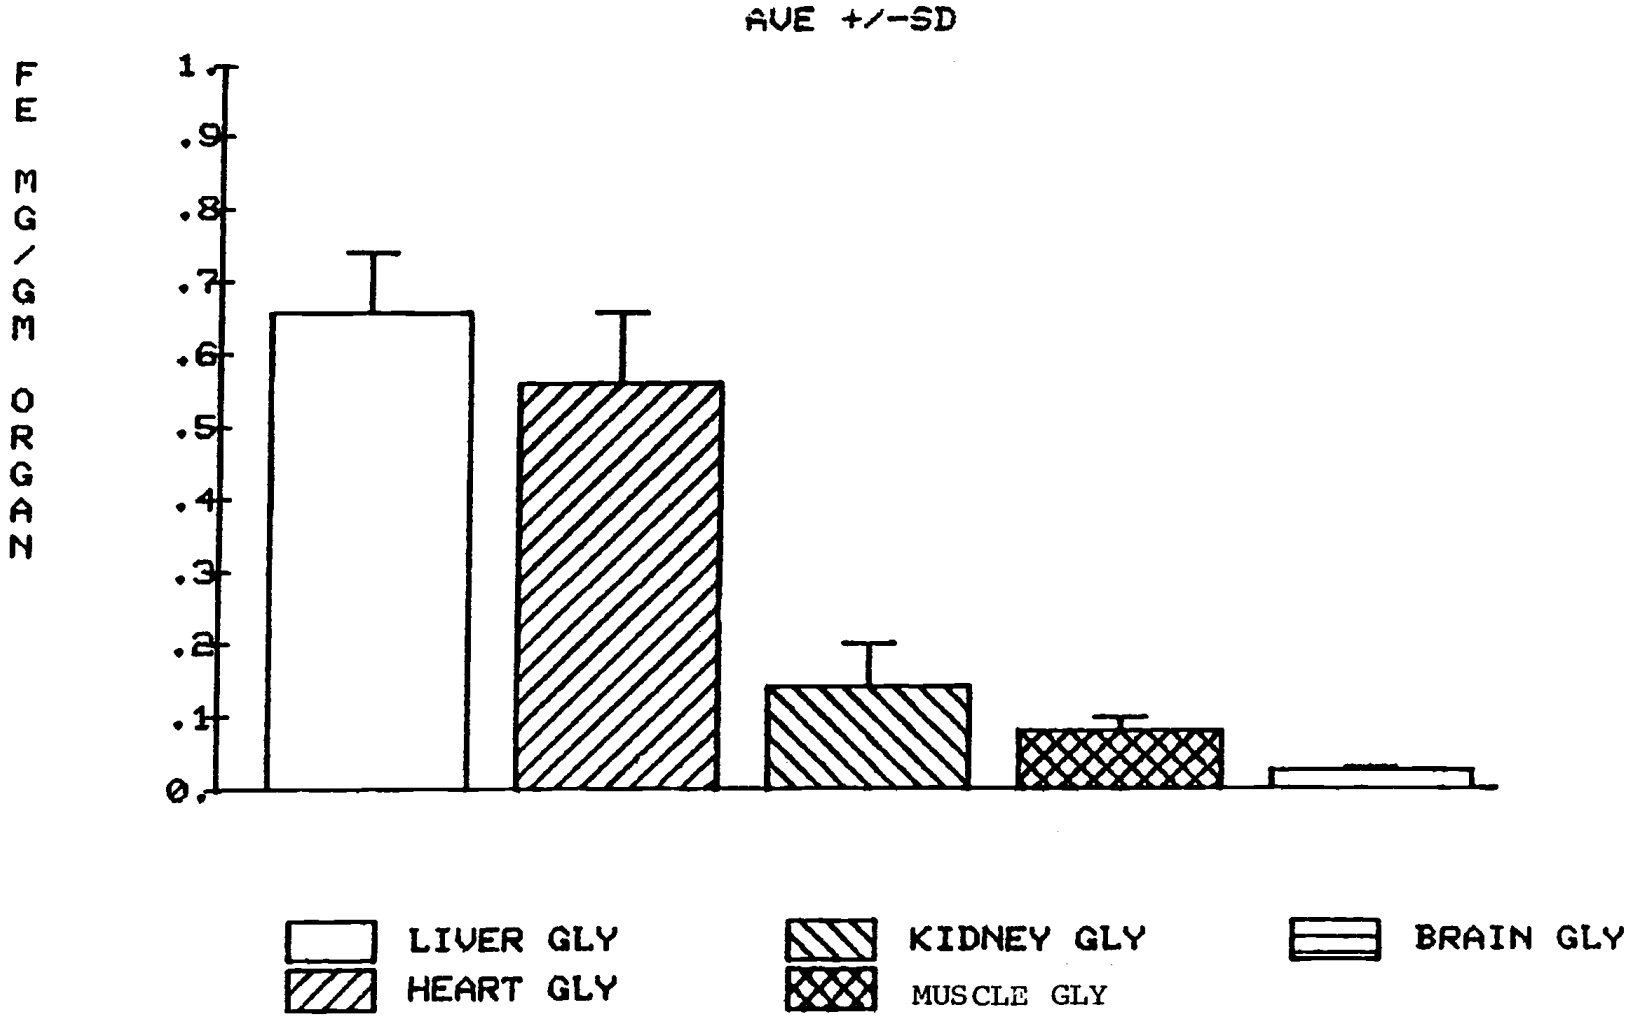

Figure B-4. Iron concentration in organs four hours after the oral administration of 0.2 M ferrous sulphate (55.6 mg/ml) and 0.4 M glycine (30.0 mg/ml).

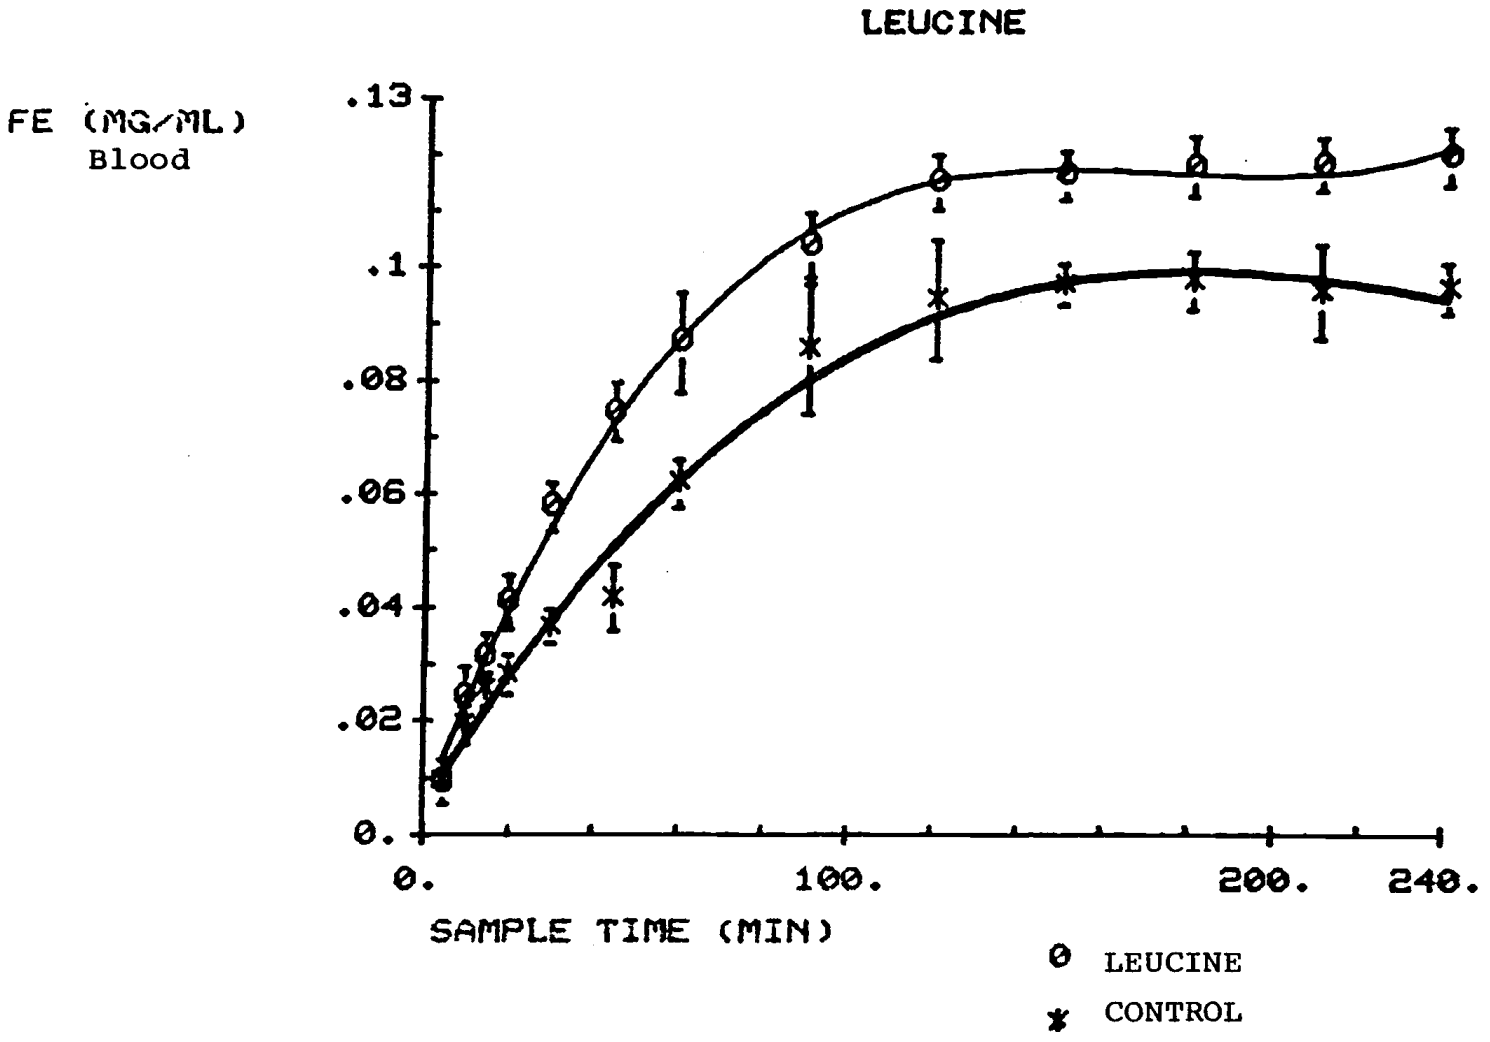

Figure B-5. Comparison of blood iron concentration when 0.2 M ferrous sulphate (55.6 mg/ml) was given as (1) control and (2) with 0.4 M leucine (52.4 mg/ml).

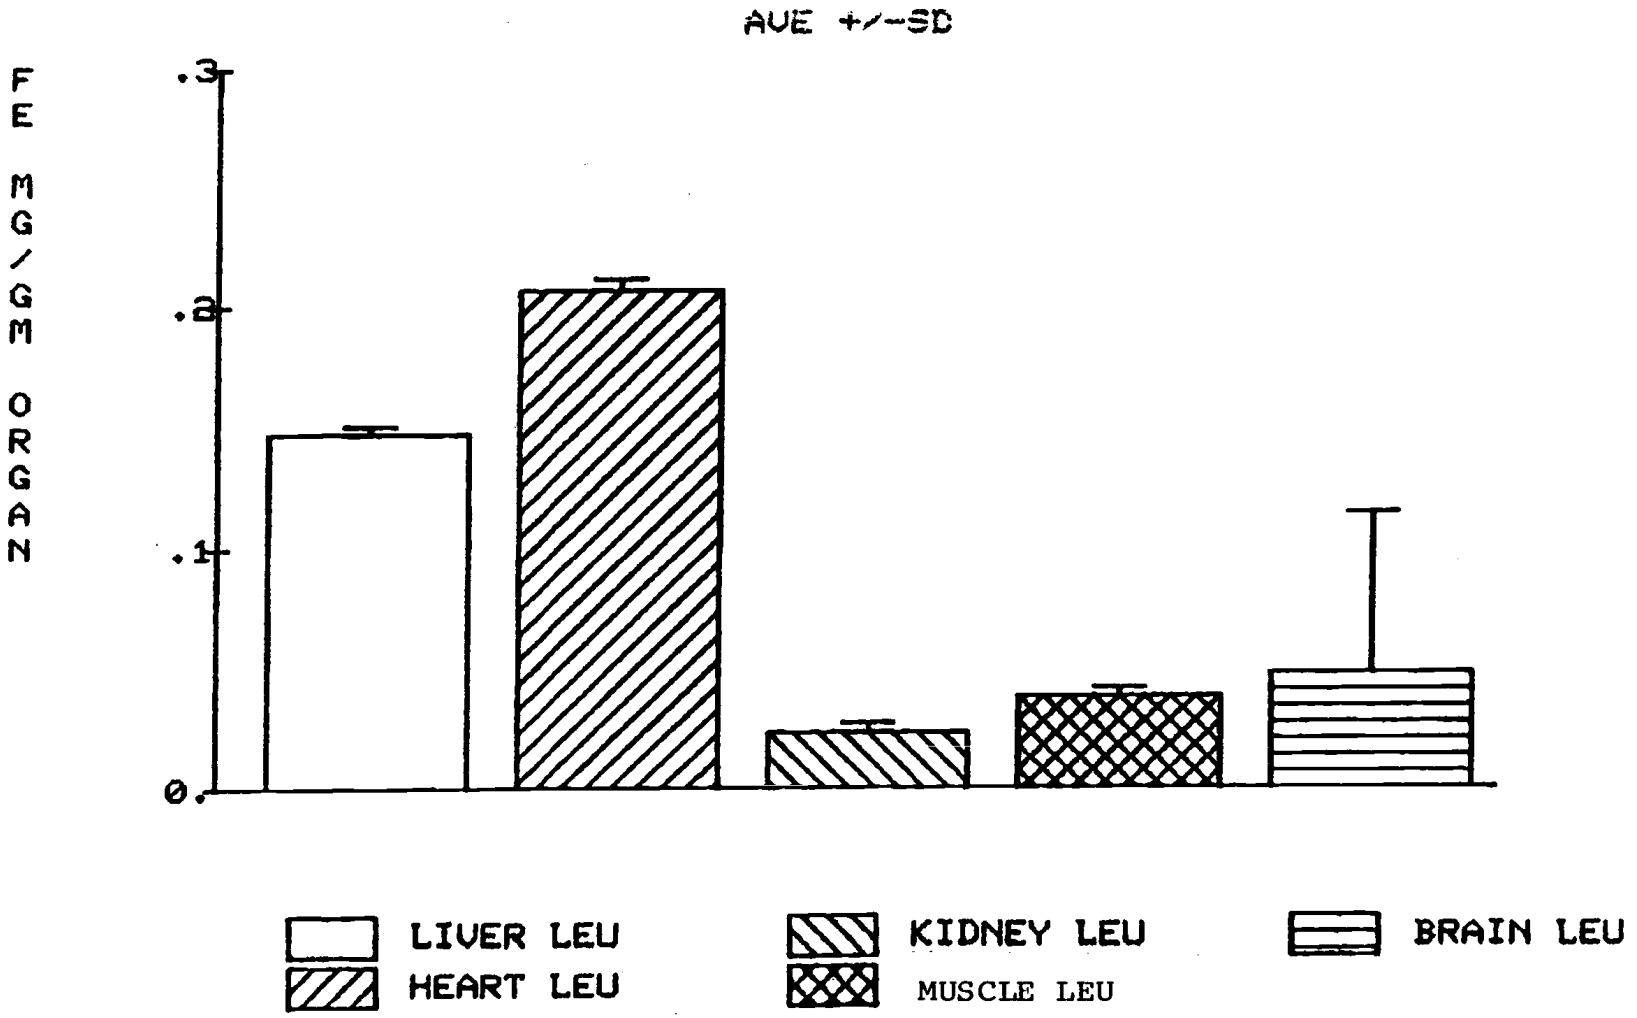

Figure B-6. Iron concentration in organs four hours after the oral administration of 0.2 M ferrous sulphate (55.6 mg/ml) and 0.4 M leucine (52.4 mg/ml).

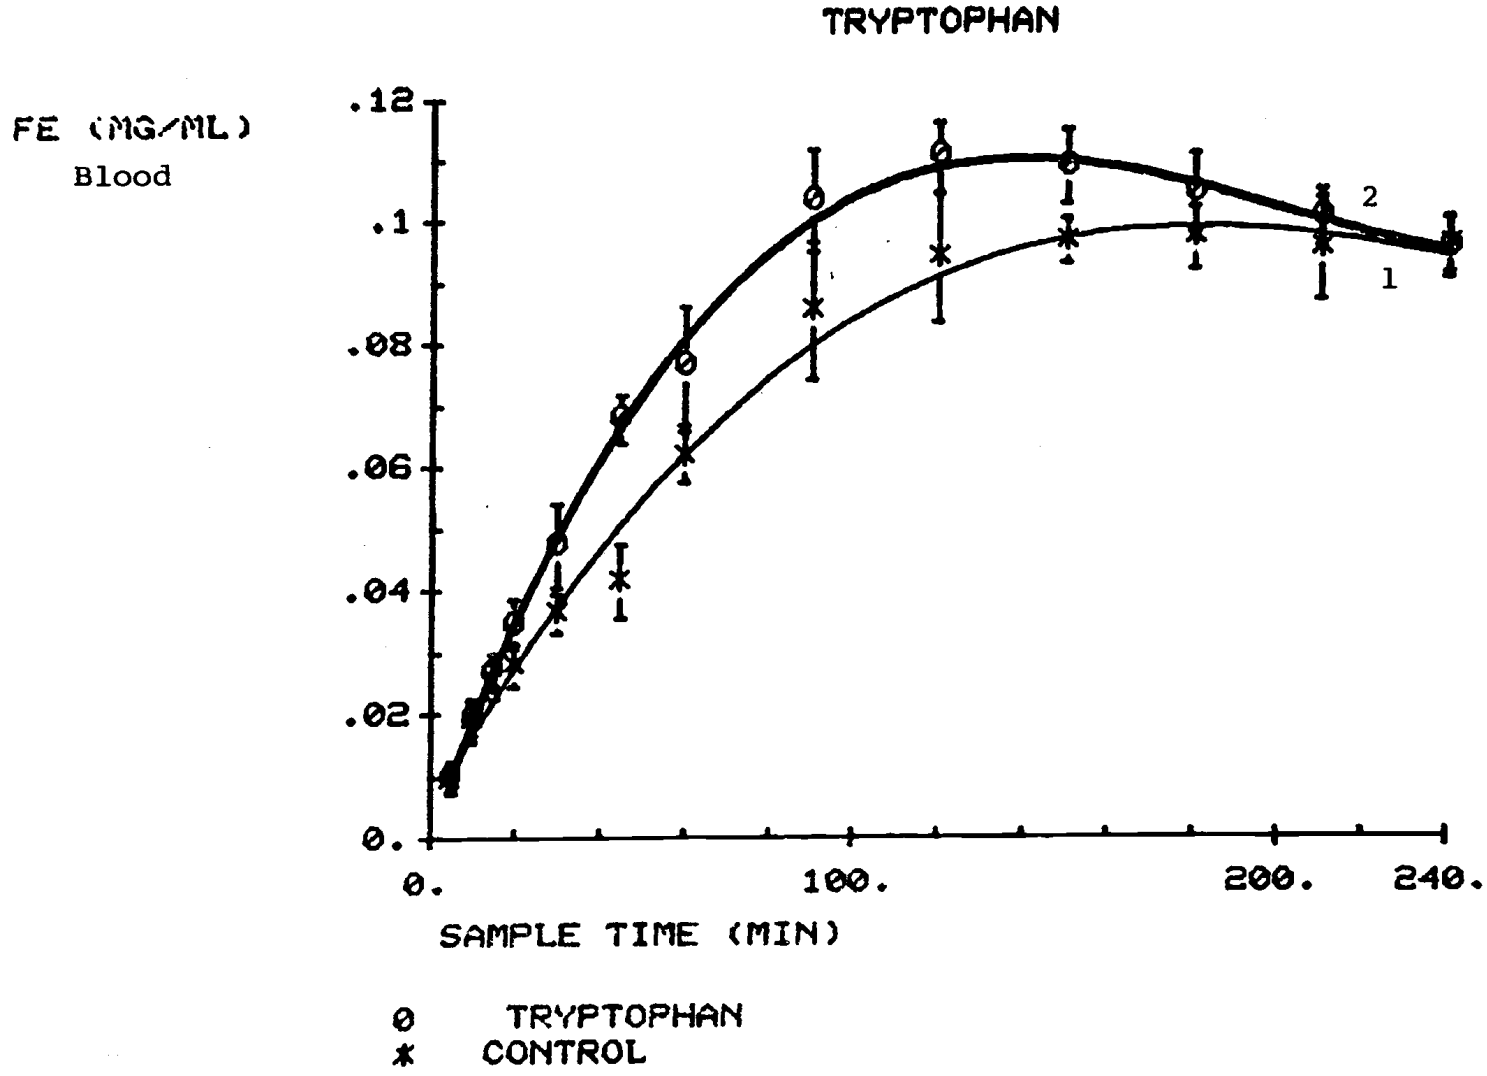

Figure B-7. Comparison of blood iron concentration when 0.2 M ferrous sulphate (55.6 mg/ml) was given as (1) control and (2) with 0.4 M tryptophan (81.2 mg/ml).

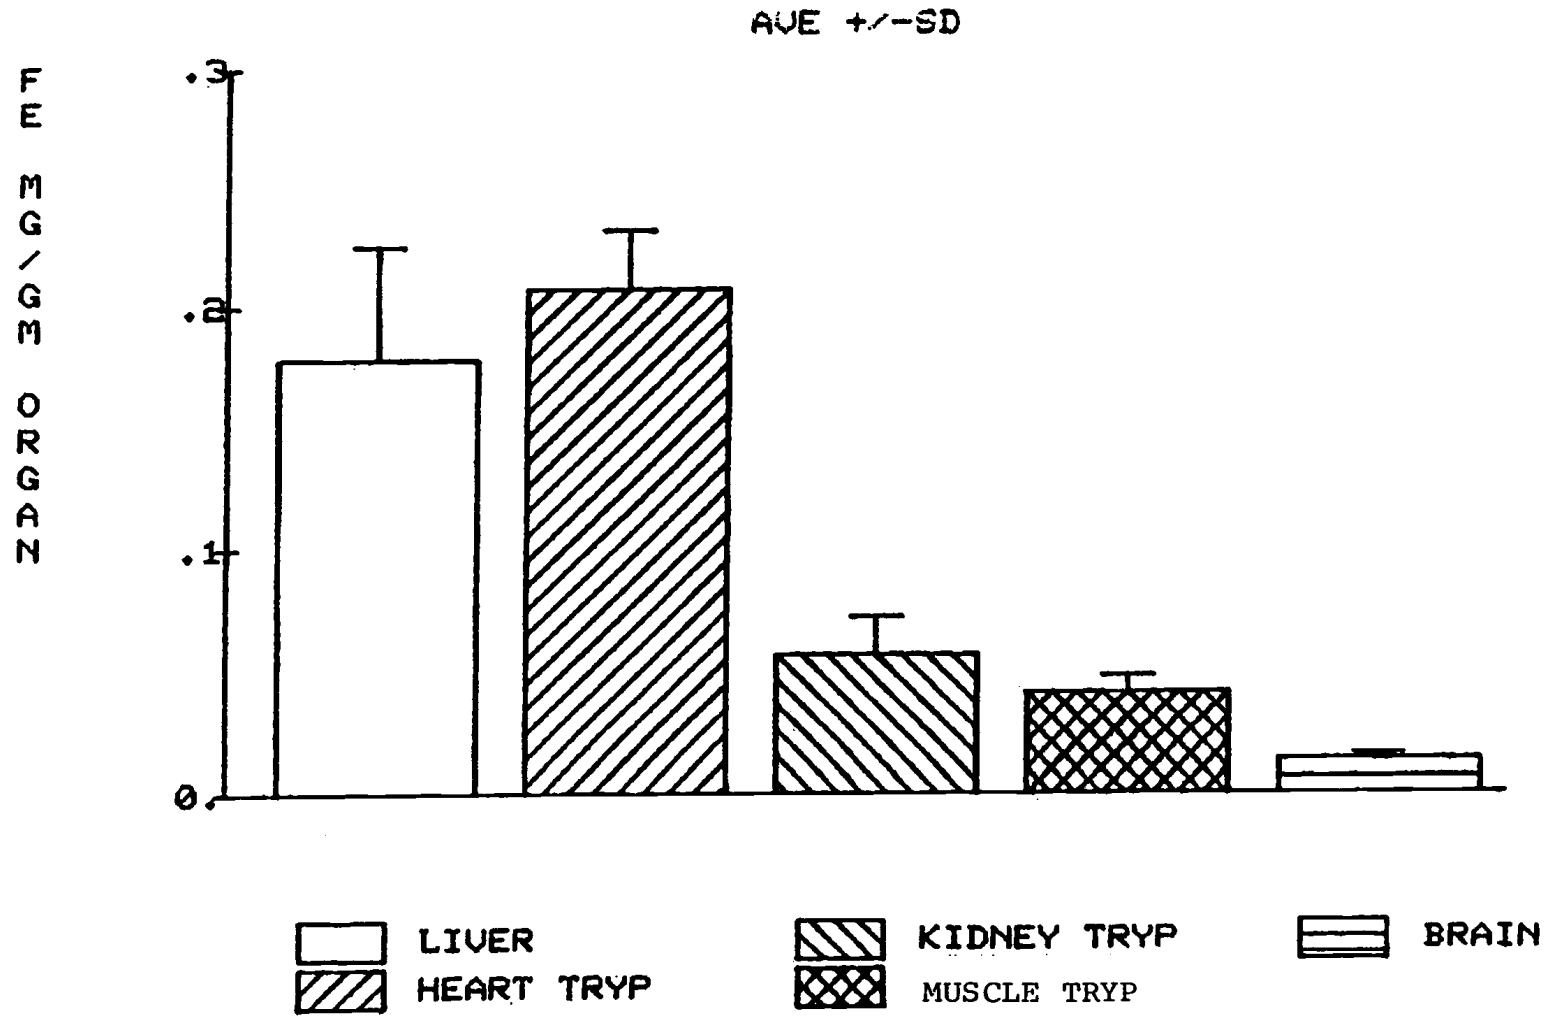

Figure B-8. Iron concentration in organs four hours after the oral administration of 0.2 M ferrous sulphate (55.6 mg/ml) and 0.4 M tryptophan (81.2 mg/ml).

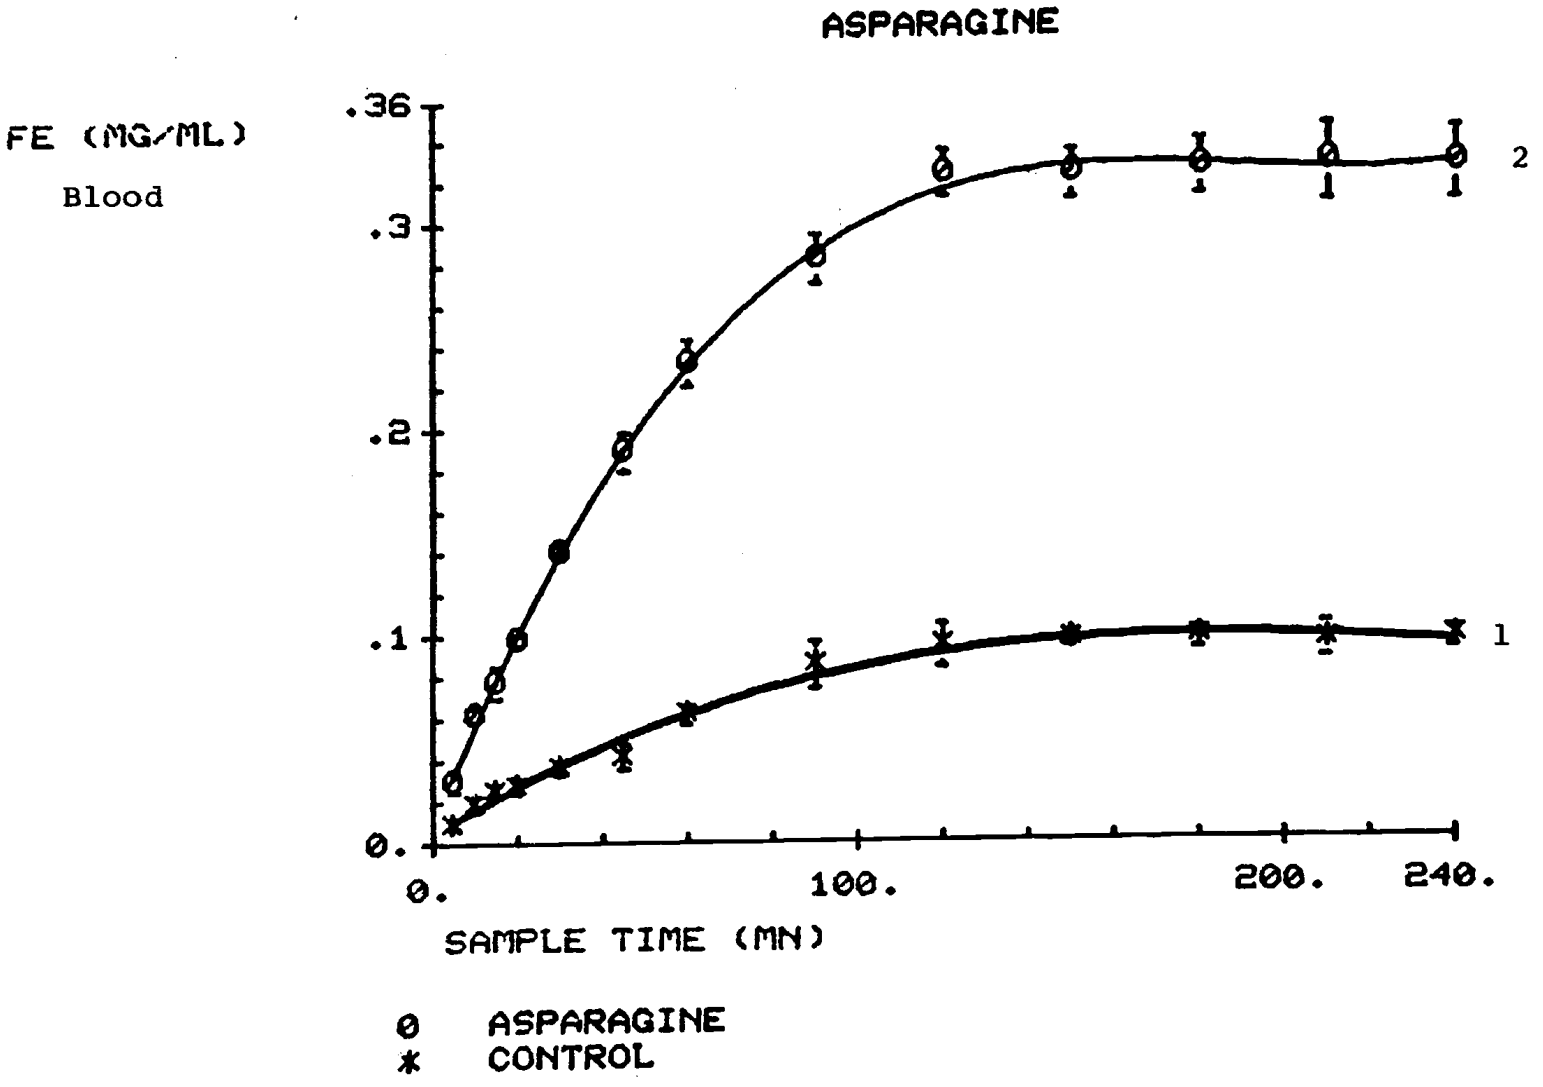

Figure B-9. Comparison of blood iron concentration when 0.2 M ferrous sulphage (55.6 mg/ml) was given as (1) control and (2) with 0.4 M asparagine (52.8 mg/ml).

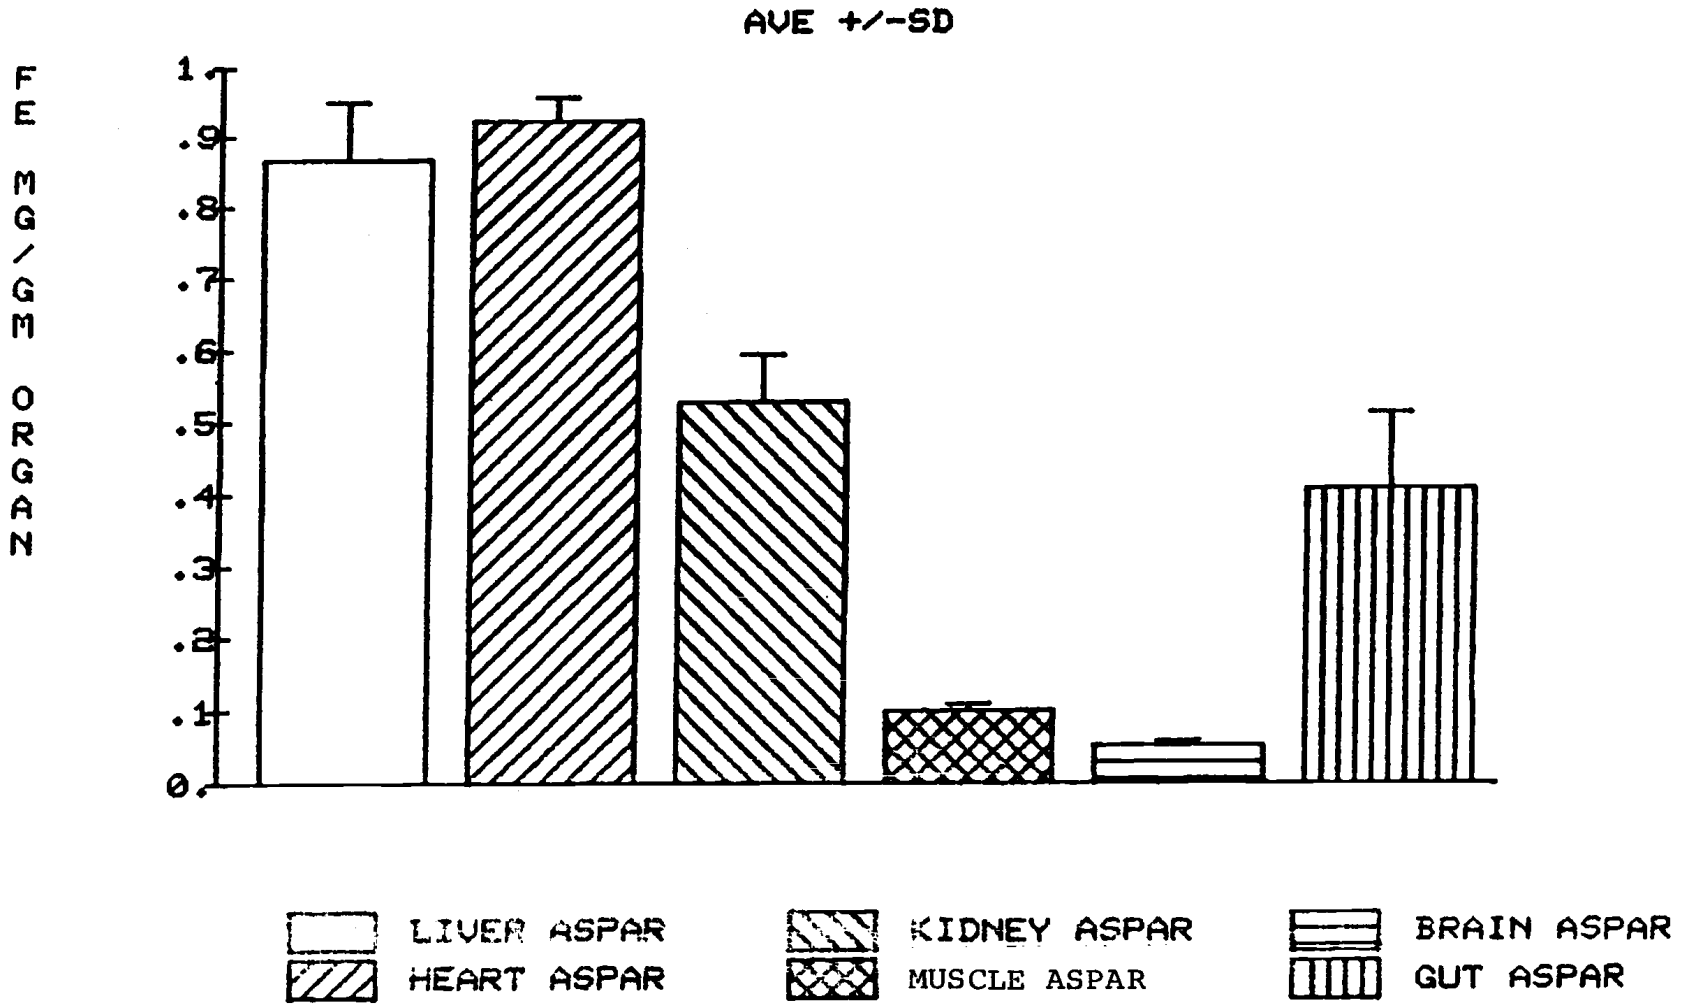

Figure B-10. Iron concentration in organs four hours after the oral administration of 0.2 M ferrous sulphage (55.6 mg/ml) and 0.4 M asparagine (52.8 mg/ml).

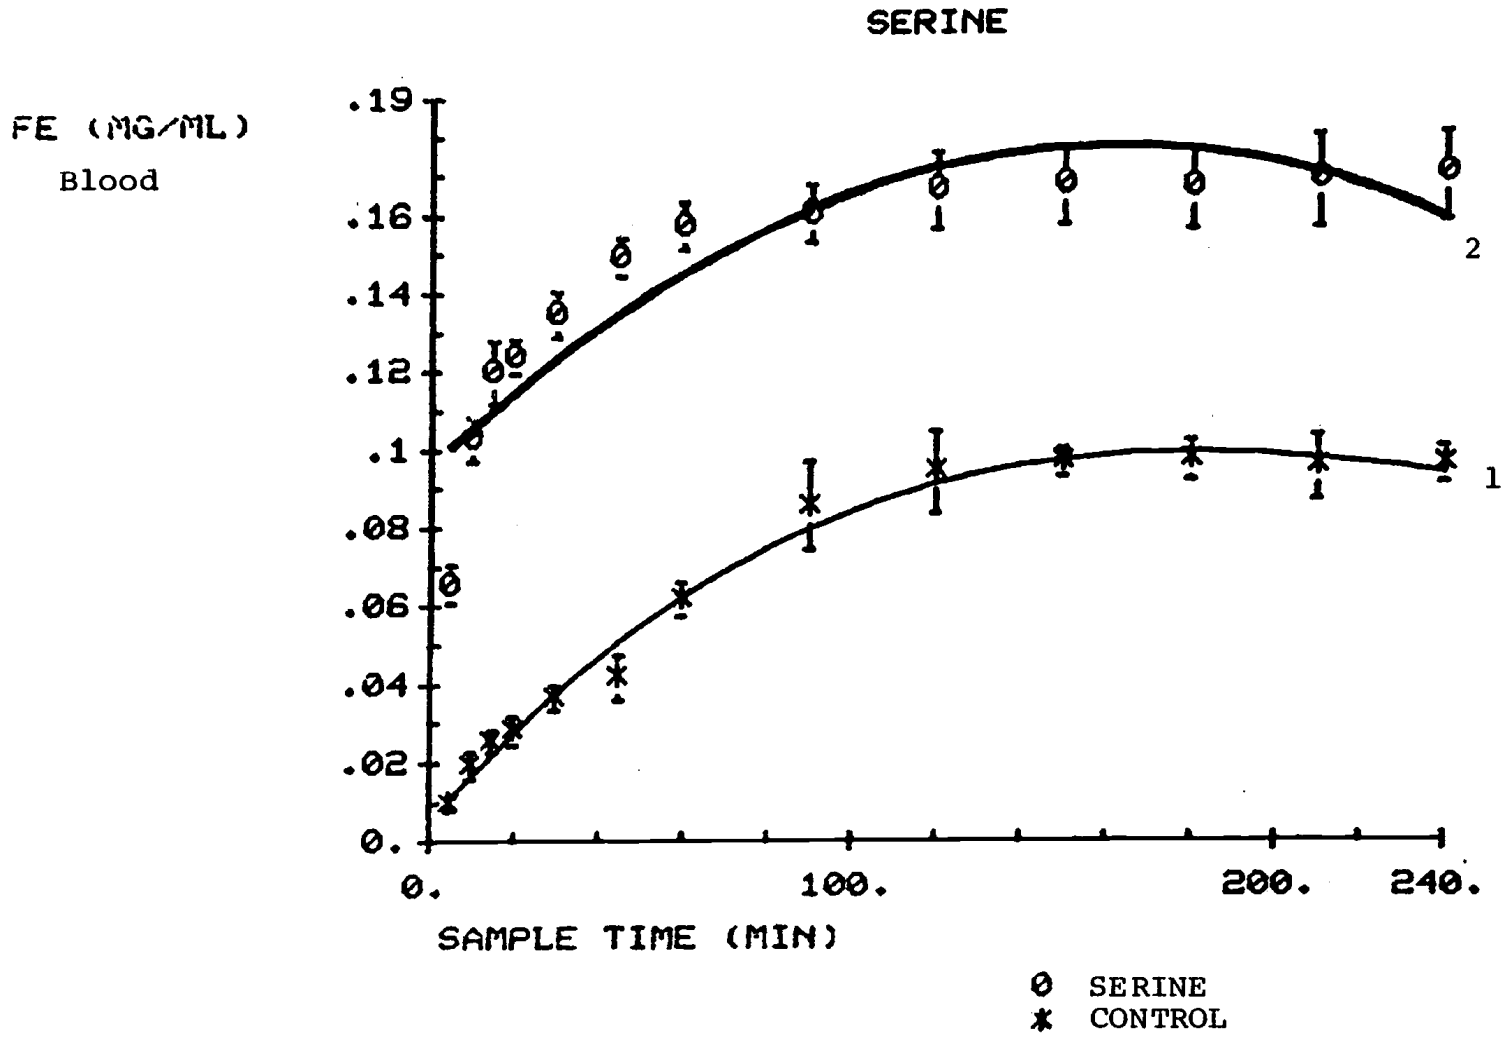

Figure B-11. Comparison of blood iron concentration when 0.2 M ferrous sulphate (55.6 mg/ml) was given as (1) control and (2) with 0.4 M serine (43.6 mg/ml).

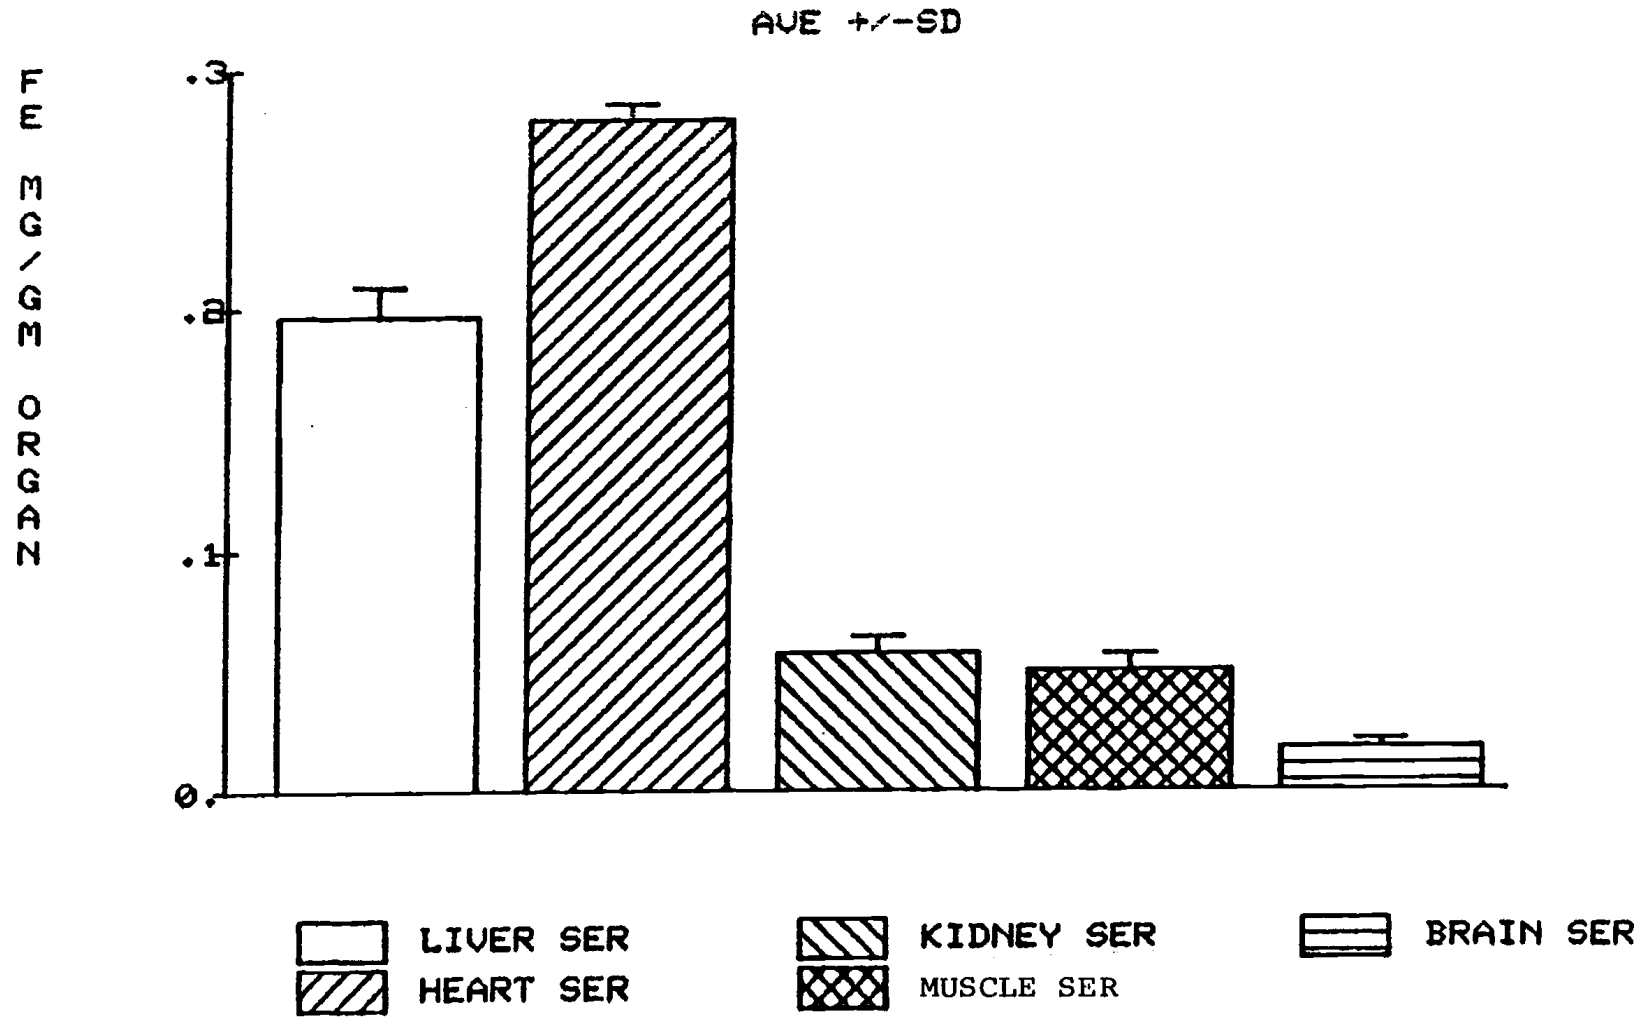

Figure B-12. Iron concentration in organs four hours after the oral administration of 0.2 M ferrous sulphage (55.6 mg/ml) and 0.4 M serine (43.6 mg/ml).

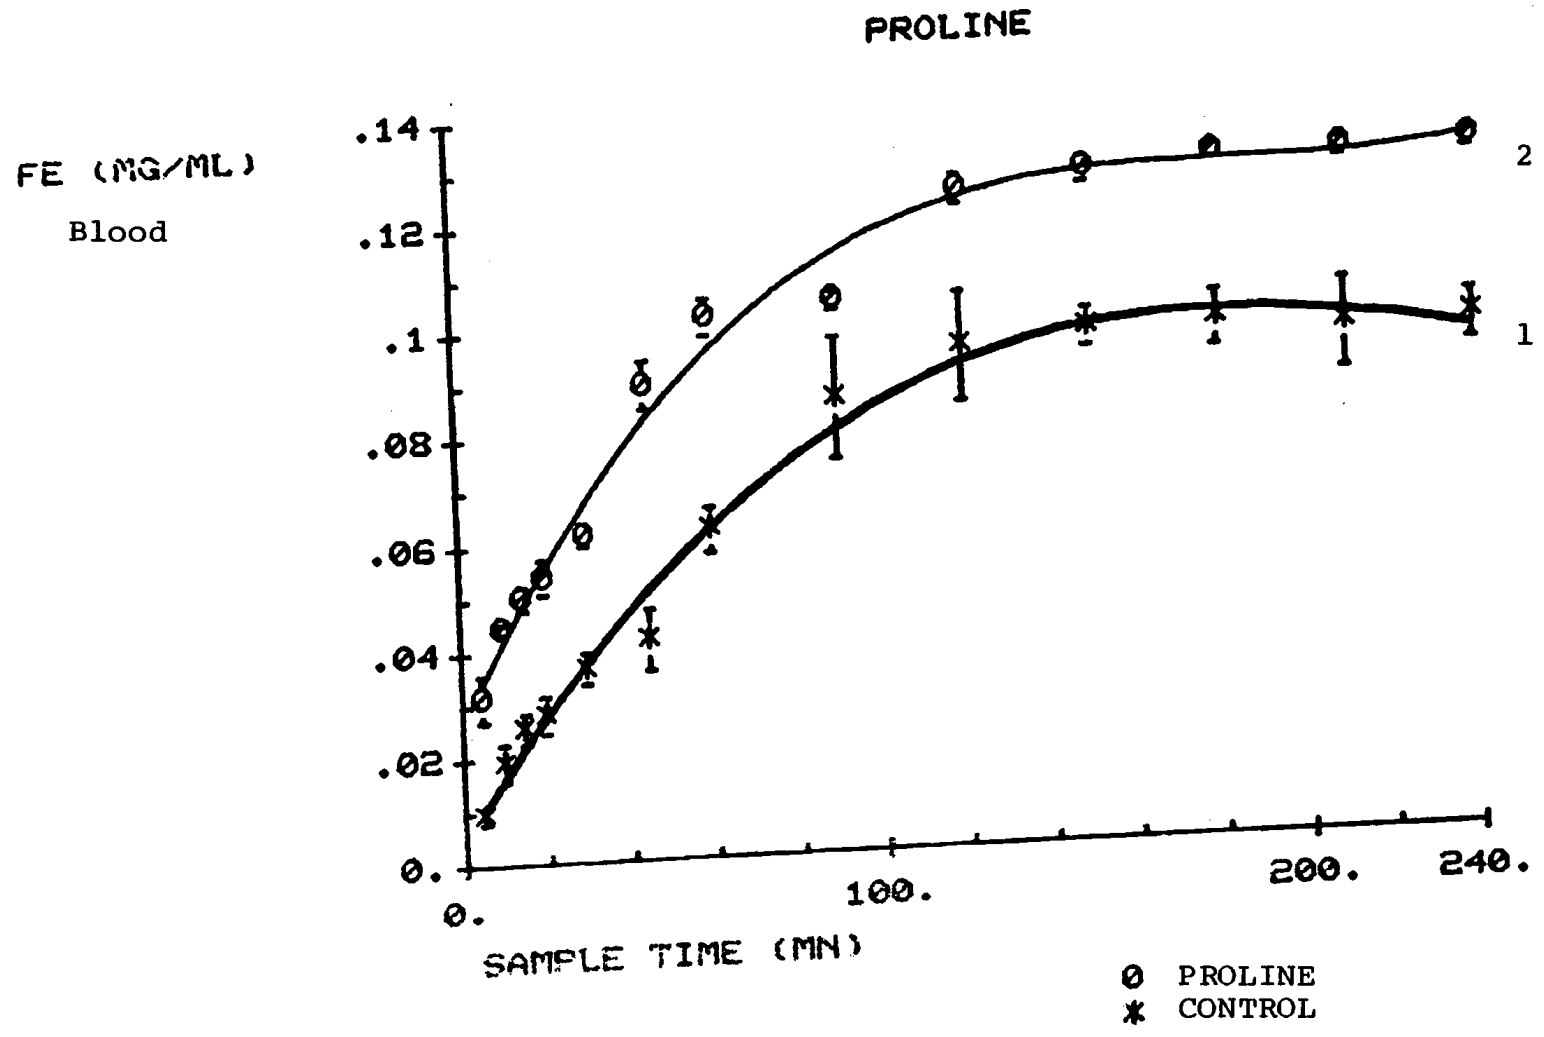

Figure B-13. Comparison of blood iron concentration when 0.2 M ferrous sulphate (55.6 mg/ml) was given as (1) control and (2) with 0.4 M proline (45.6 mg/ml).

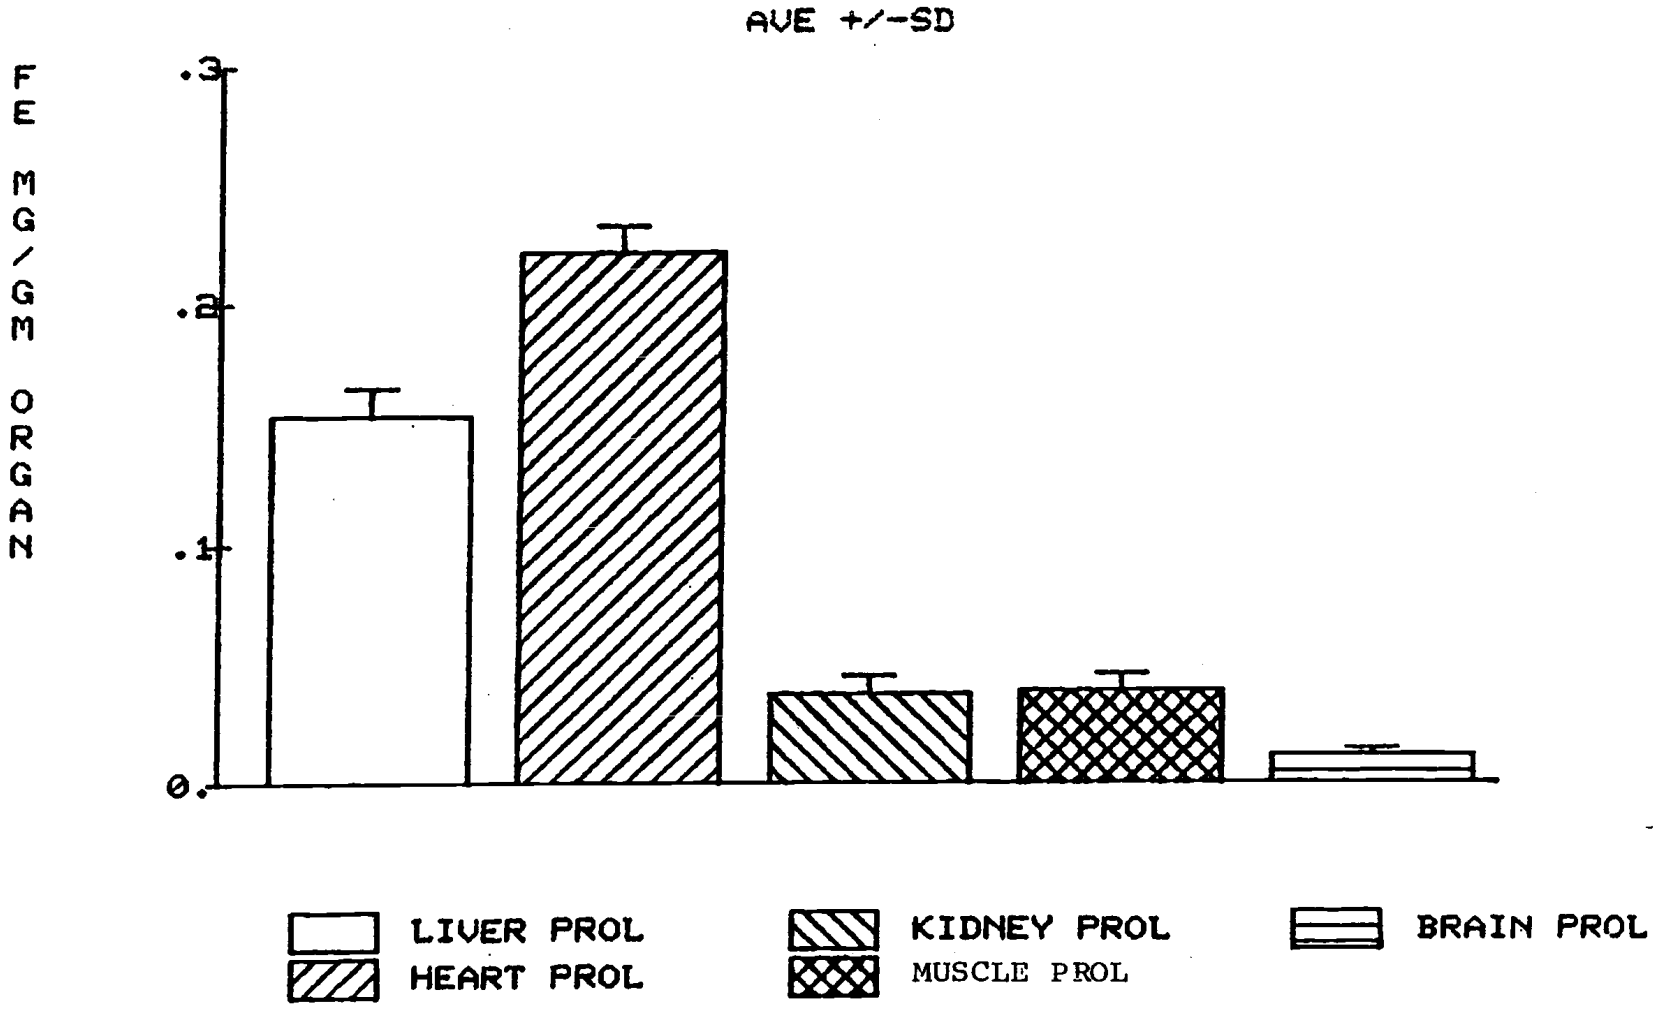

Figure B-14. Iron concentration in organs four hours after the oral administration of 0.2 M ferrous sulphate (55.6 mg/ml) and 0.4 M proline (45.6 mg/ml).

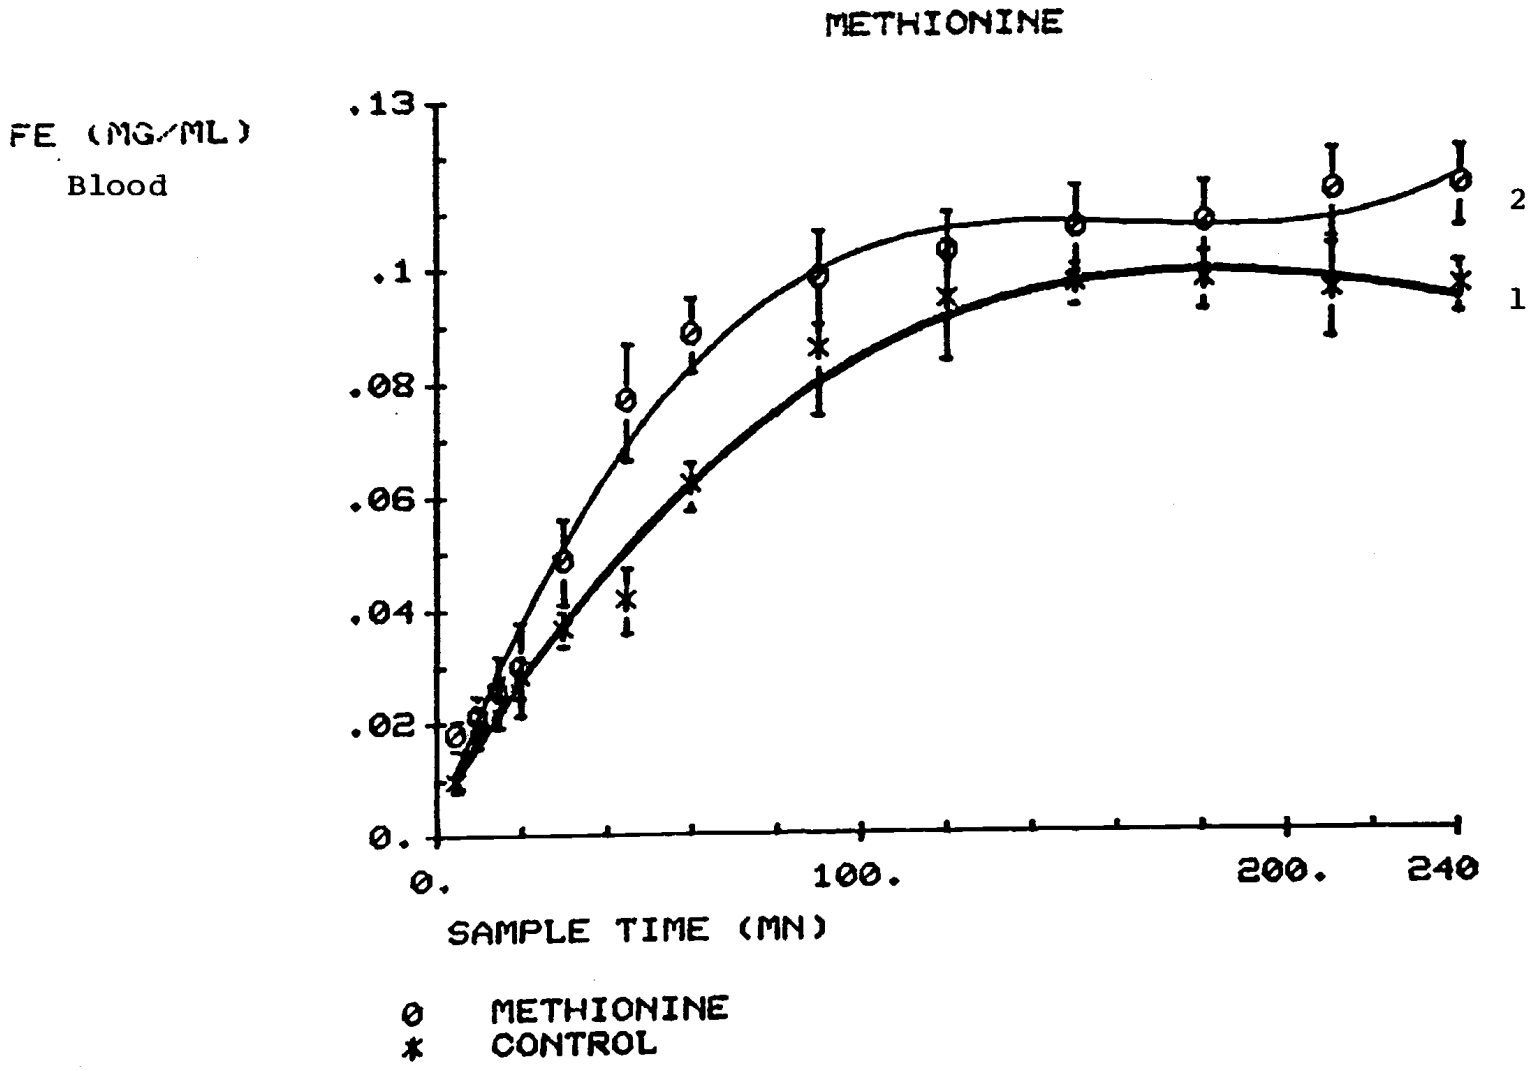

Figure B-15. Comparison of blood iron concentration when 0.2 M ferrous sulphate (55.6 mg/ml) was given as (1) control and (2) with 0.4 M methionine (59.6 mg/ml).

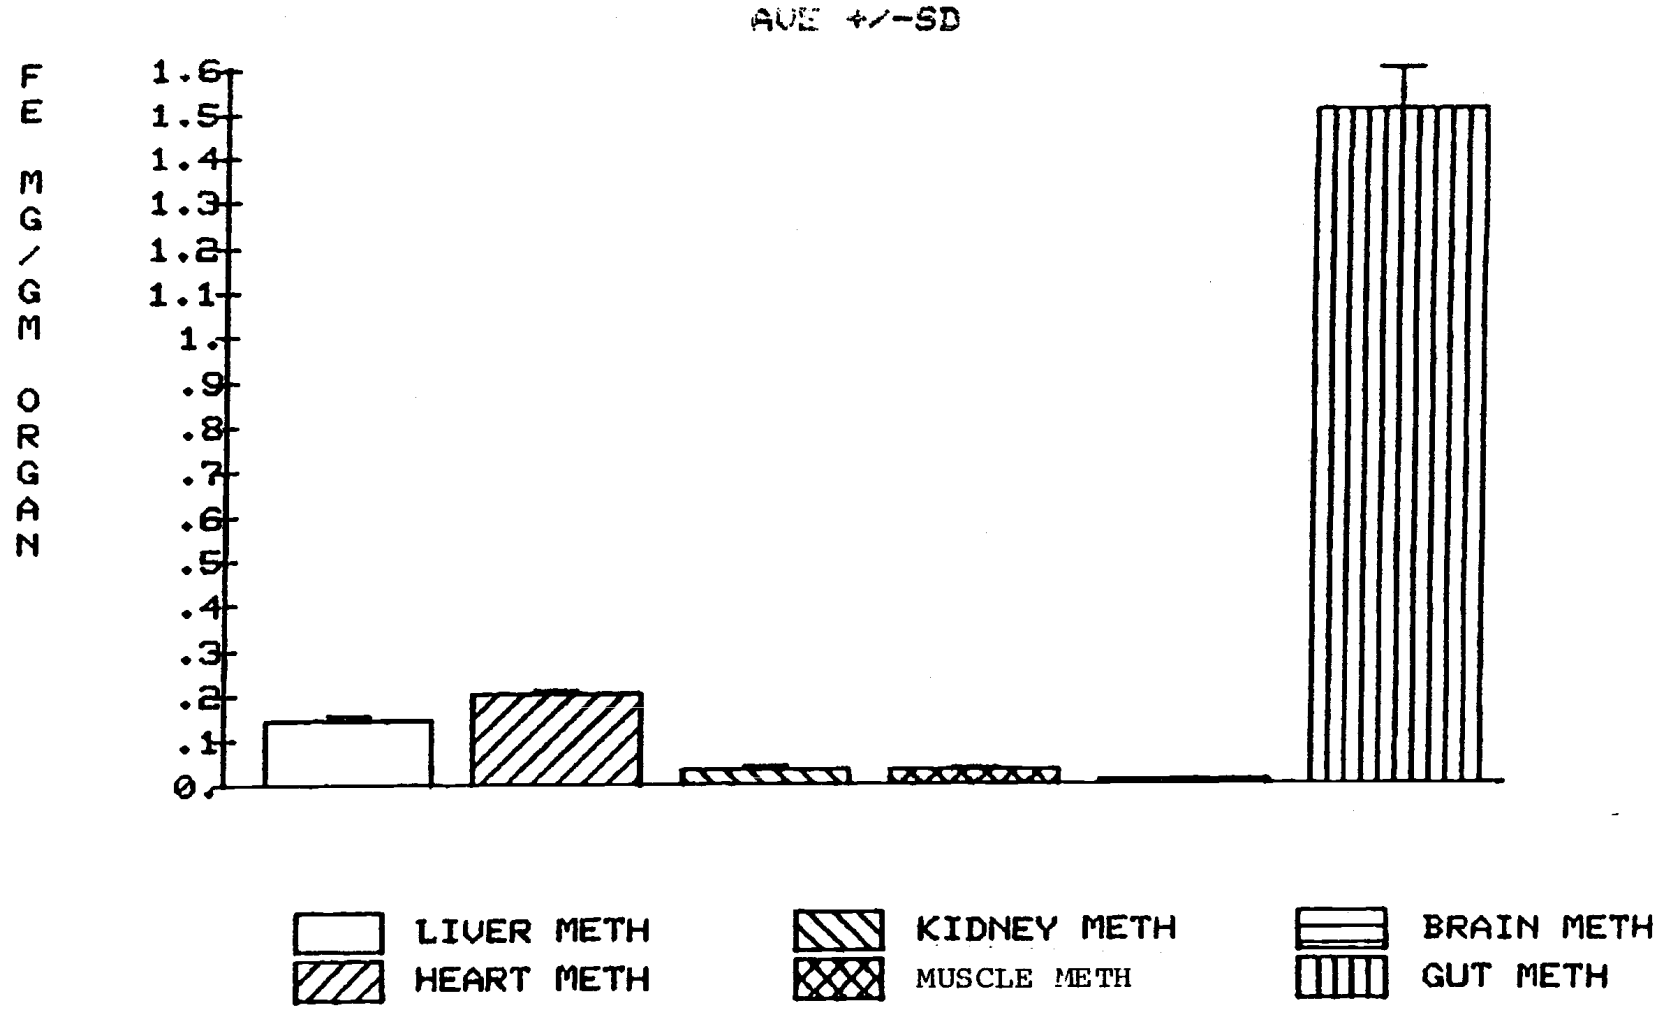

Figure B-16. Iron concentration in organs four hours after the oral administration of 0.2 M ferrous sulphate (55.6 mg/ml) and 0.4 M methionine (59.6 mg/ml).

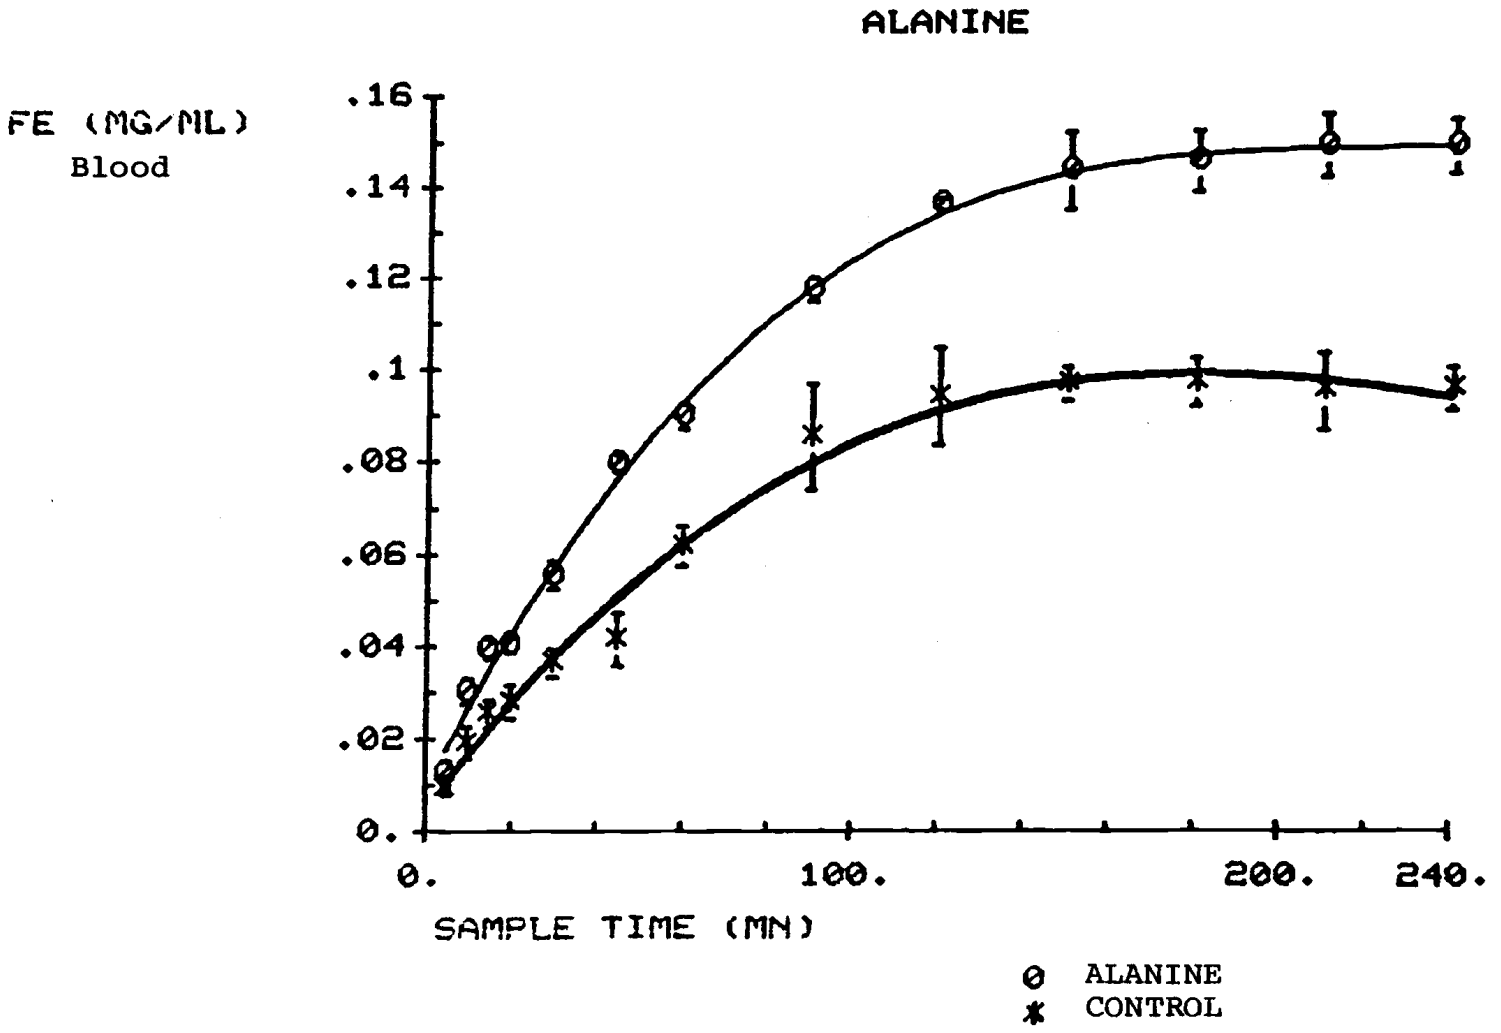

Figure B-17. Comparison of blood iron concentration when 0.2 M ferrous sulphate (55.6 mg/ml) was given as control and when it was administered with 0.4 M alanine (35.6 mg/ml).

Figure B-18. Iron concentration in organs four hours after the oral administration of 0.2 M ferrous sulfate (55.6 mg/ml) and 0.4 M alanine (35.6 mg/ml).

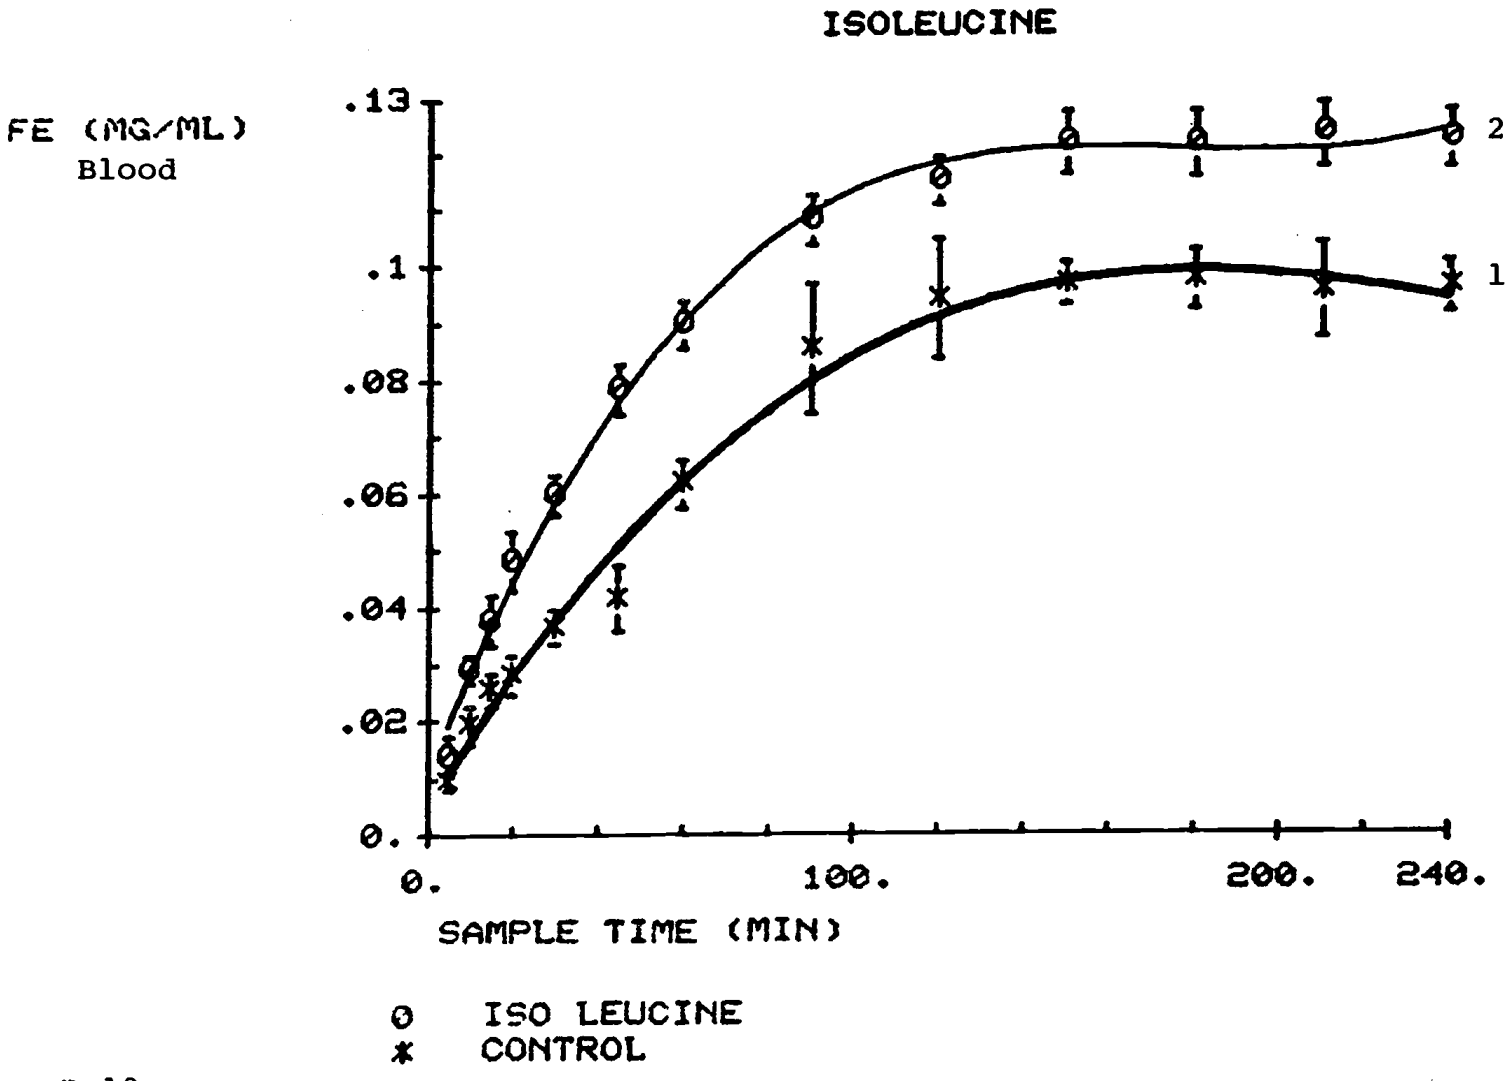

Figure B-19. Comparison of blood iron concentration when 0.2 M ferrous sulphate (55.6 mg/ml) was given as (1) control and (2) with 0.4 M isoleucine (52.4 mg/ml).

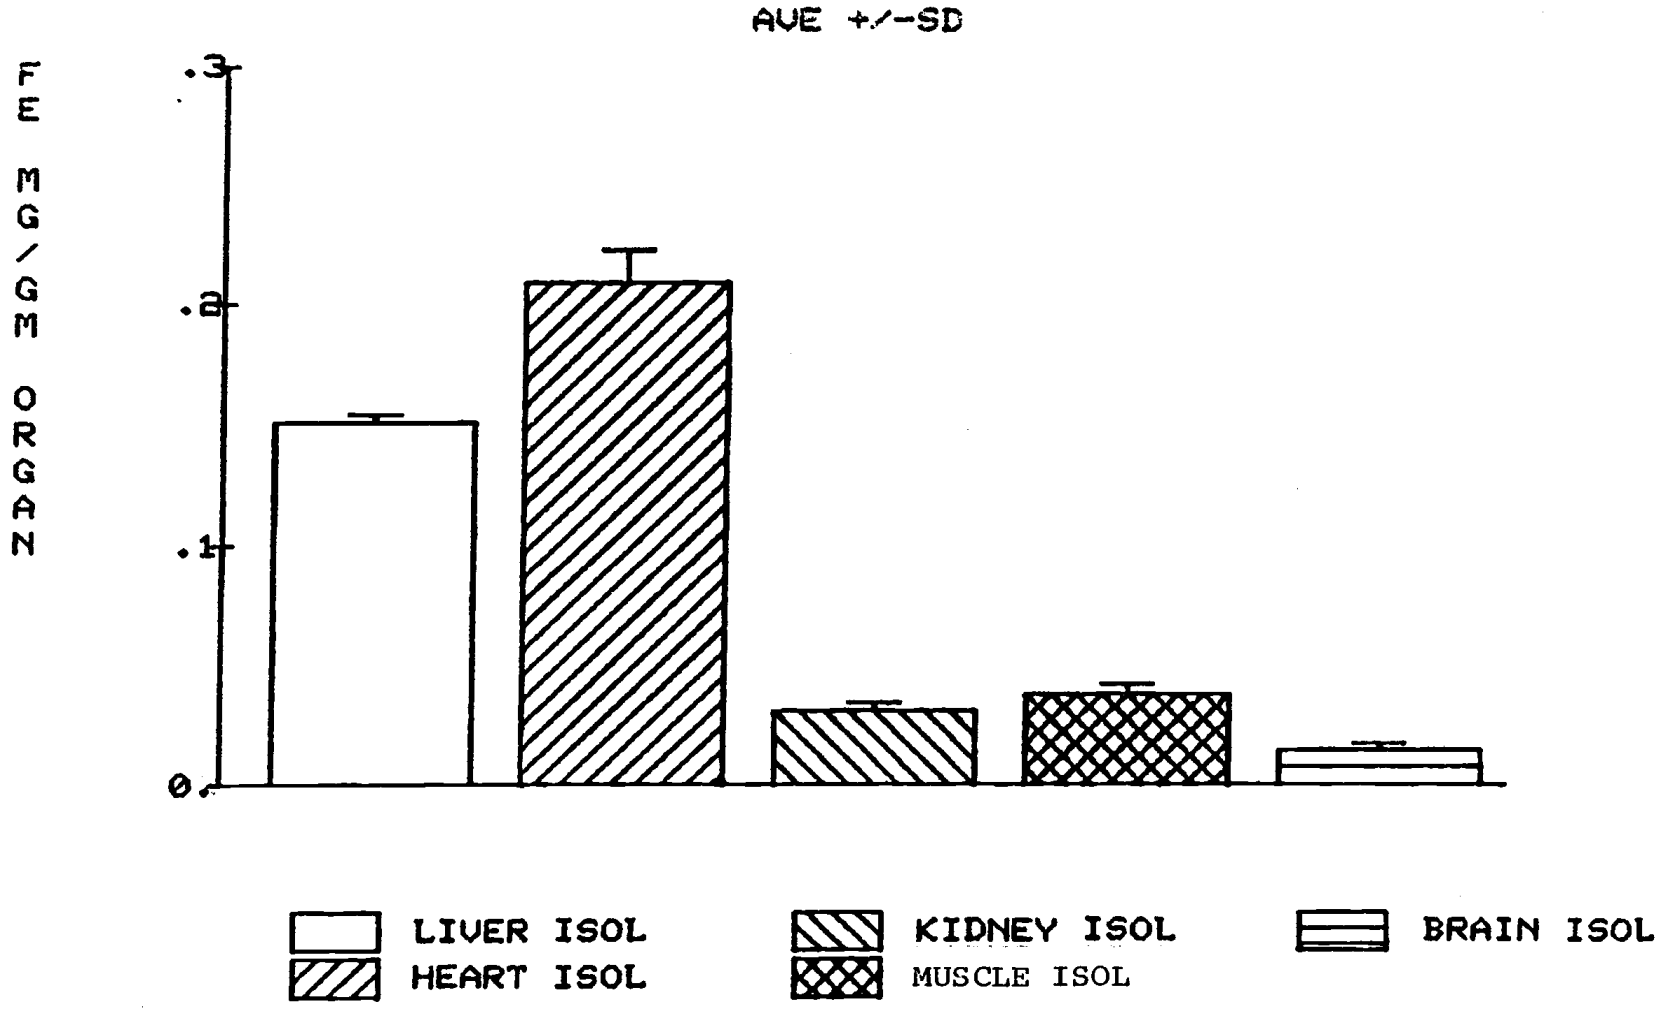

Figure B-20. Iron concentration in organs four hours after the oral administration of 0.2 M ferrous sulphate (55.6 mg/ml) and 0.4 M isoleucine (52.4 mg/ml).

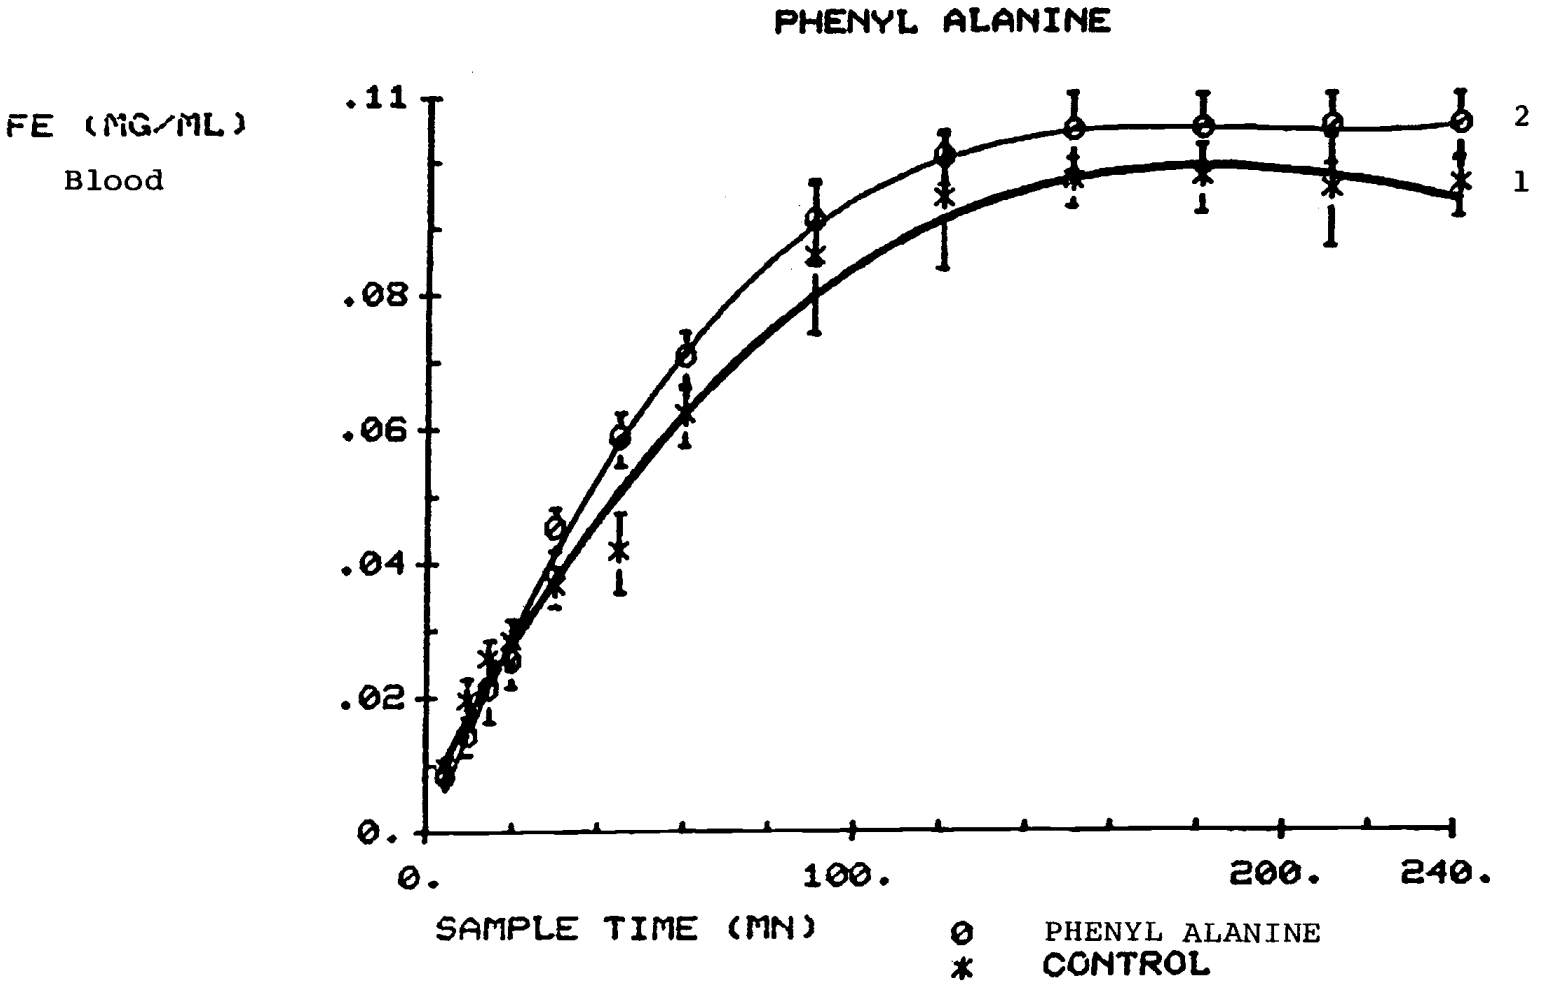

Figure B-21. Comparison of blood iron concentration when 0.2 M ferrous sulphate (55.6 mg/ml) was given as (1) control and (2) with 0.4 M phenylalanine (66.0 mg/ml).

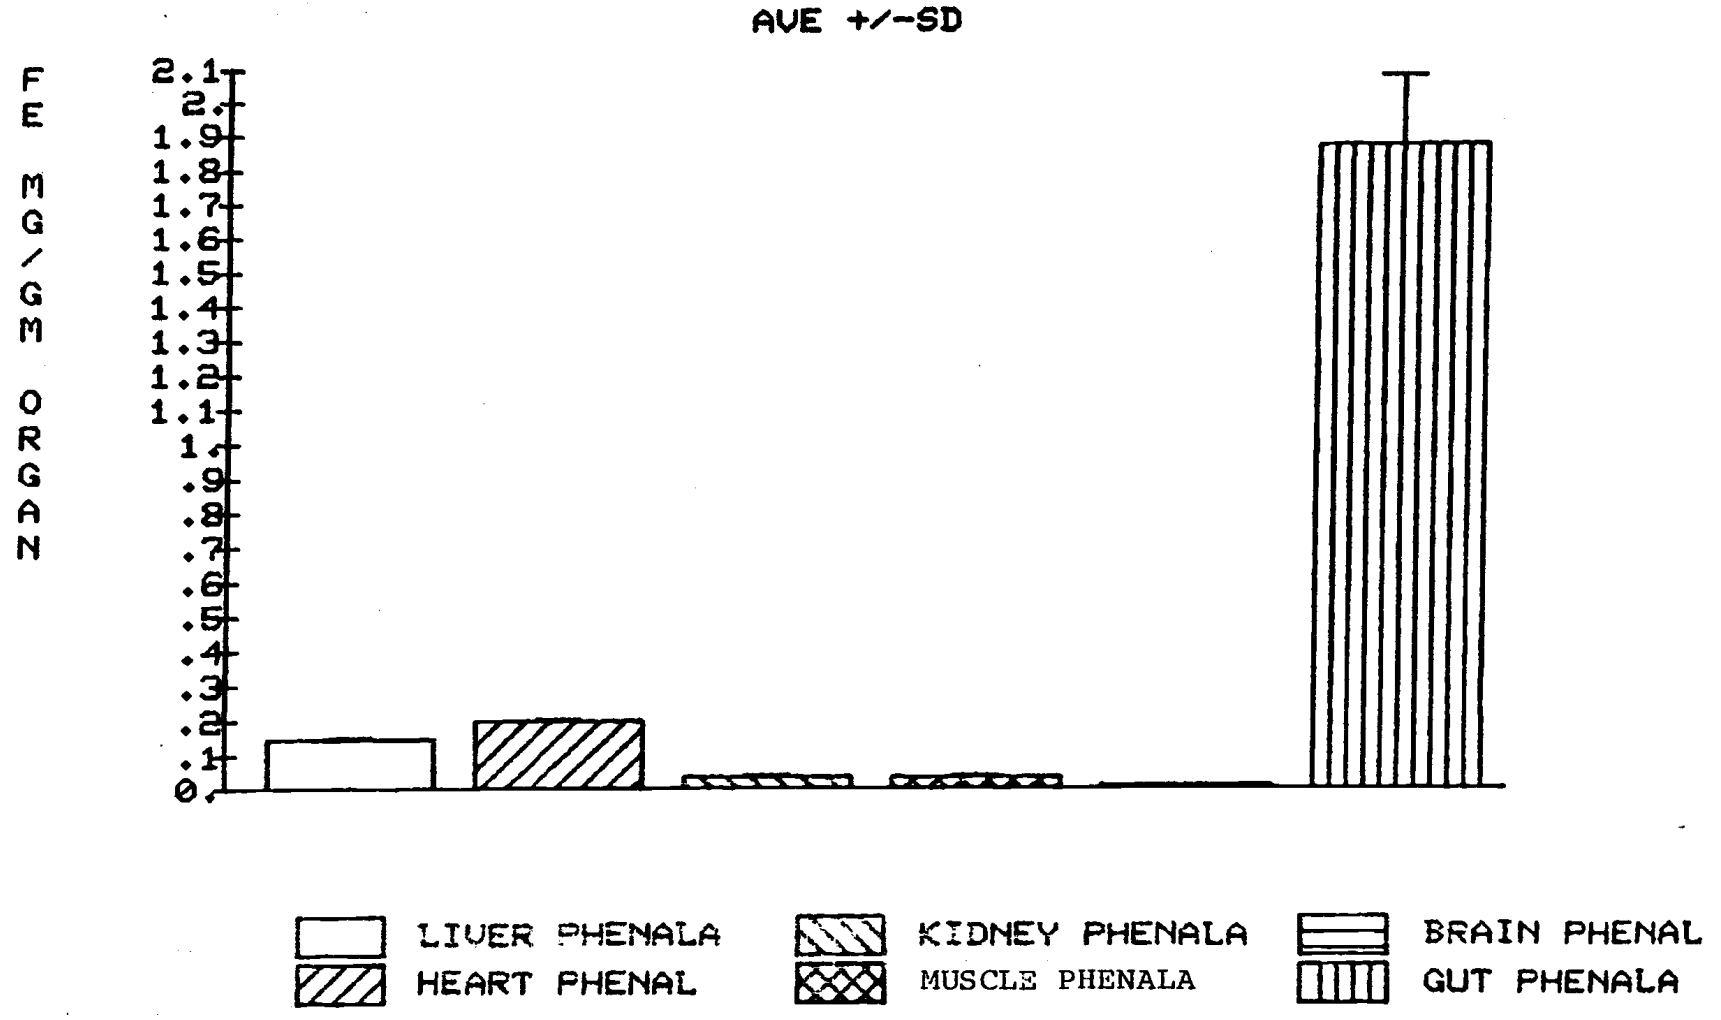

Figure B-22. Iron concentration in organs four hours after the oral administration of 0.2 M ferrous sulphate (55.6 mg/ml) and 0.4 M phenylalanine (66.0 mg/ml).

Appendix C

STABILITY CONSTANT EQUATIONS

1. $K_s = K_1 K_2$

2. $K_1 = \dfrac{\bar{n}}{(1-\bar{n})[Sc]}$

   Sc = the concentration of free chelating species

   $\bar{n}$ = the average number of molecules of complex forming agent bound by one atom of metal

3. $\text{Log}[Sc] = \log\{[HSc°] - [KOH] - [H^+] + [OH^-]\} - \log\{\dfrac{[H^+]}{Ka} + \dfrac{2[H^+]^2}{KaKa'}\}$

   [HSc°] = concentration of complex-forming agent (all species), before the metal was added.

   [KOH] = concentration of KOH which would be present if the complex forming agent and metal were absent

4. $\text{Log}[Sc] = (pH - pKa) + \log\{[HSc°] - [KOH]\}$

5. $\bar{n} = \dfrac{[HSc°] - \alpha[Sc]}{[M°]}$

   [M°] = total concentration of the metal (free or combined).

6. $\alpha = \dfrac{[H^+]}{Ka} + 1$

   $\alpha = \dfrac{[H^+]}{Ka} + \dfrac{[H^+]^2}{KaKa'} + 1$

7. $\bar{n} = \frac{2[KOH]}{[HSc^{\circ}]}$ (simplified)

8. $Ks = \frac{1}{[Sc]^2}$ valid only when $\bar{n} = 1$

i.e., $\log Ks = -2 \log[Sc]$

Sample Calculation

Iron-glycine complex

When adding 0.25 ml of KOH for example, the pH was 7.17

$$\log[Sc] = (7.17 - 9.17) + \log[(5\times10^{-4}) - (0.2621\times10^{-4})] = -5.85$$

when n = 1 $\log[Sc] = -3.8$

$\therefore Sc = 1.58\times10^{-4}$

$$K_s = \frac{1}{[Sc]^2} = \frac{1}{(1.58\times10^{-4})^2} = 0.4\times10^{8}$$

$\therefore \log K_s = 7.60$

Appendix D

POLYVIALS CLEANING PROCEDURE

1. Wash polyvials with 2N nitric acid for 10 minutes using "ultrasonic" cleaner.[12]
2. Rinse polyvials with distilled water for several times.
3. Wash polyvials with absolute (95%) ethanol in "Ultrasonic" for about 10 minutes.
4. Drain the alcohol and wash with acetone for 10 minutes.
5. Air dry polyvials on a clean sheet in "clean" room equipped with laminar flow filter.
