AN ABSTRACT OF THE THESIS OF

Katharine Danielle Sarmast for the degree of Master of Science in Radiation Health Physics presented on November 19, 2010.

Title: MCNP5 Modeling of the Oregon State TRIGA® Reactor for SkyShine Dose Estimation After a Loss of Coolant Accident

Abstract approved:

Steve R. Reese

This thesis evaluates dose rates from the TRIGA® reactor by comparing ion chamber measured exposure rates to exposure rates calculated from MCNP5 model data. The first step evaluates the energy distribution required to match ion chamber exposure rates from measurements taken at 1 foot increments above the reactor core. Next, the back calculated source activity is used to determine the exposure rates, at those same 1 ft increments above the core, in the event of a loss of coolant accident (LOCA). Then the energies deposited in simulated ion chambers, above the core are used to determine the dose rate to a person standing on top of the reactor bioshield after a LOCA. The dose rates that are calculated using the MCNP5 data were compared to calculations from the Oregon State TRIGA® Reactor (OSTR) Safety Analysis Report (SAR). The final step is to determine the maximum dose rate at the OSTR facility perimeter after a LOCA, due to skyshine.

The MCNP5 results showed that OSTR SAR overestimates dose rates at the top of the reactor bioshield. The discrepancy stems from the OSTR SAR using worst case scenario data, while this report uses less conservative, yet accurate, assumptions. The instantaneous dose rates on the reactor building exterior from photon skyshine peak at approximately 30 mrem per hour. The integrated activity resulted in a dose rate of approximately .005 mrem within the first hour after the reactor has shut down.

MCNP5 Modeling of the Oregon State TRIGA® Reactor for SkyShine Dose Estimation After a Loss of Coolant Accident

A THESIS

Submitted to

Oregon State University

in partial fulfillment of
the requirements for the
degree of

Master of Science

Presented November 19, 2010
Commencement June 2011

Master of Science thesis of Katharine Danielle Sarmast presented on November 19, 2010.

APPROVED:

Major Professor, Representing Radiation Health Physics

Head of the Department of Nuclear Engineering and Radiation Health Physics

Dean of the Graduate School

I understand that my thesis will become part of the permanent collection of Oregon State University libraries. My signature below authorizes release of my thesis to any reader upon request.

Katharine Danielle Sarmast, Author

ACKNOWLEDGEMENTS

I would like to express my tremendous gratitude to all faculty and staff in the Nuclear Engineering and Radiation Health Physics department at Oregon State University. A special thank you goes to Dr. Steve Reese, whose assistance and guidance enabled me to complete my thesis topic. His patience is endless, and for that I am forever grateful.

I would also like to thank my family: my father Dan, who has taught me most of life's lessons; my sister Patricia and her family, who have encouraged me to get out and try different things; many other family and friends who are endless in their love and support. You are all such an integral part of my success and I love you all!

Special thanks go to my supportive husband, Waqar. He supported my decision to continue my education by moving halfway across the country with me, allowing me to attend OSU as an on campus student. With his encouragement and love, I am moving forward into a promising and bright future.

MCNP5 Modeling of the Oregon State TRIGA® Reactor for SkyShine Dose Estimation After a Loss of Coolant Accident

1. Introduction

1.1 Research Objective

The objective of this thesis is to estimate photon dose rates, attributable to skyshine, from the Oregon State University TRIGA® reactor (OSTR) generated during a LOCA. Maximum dose rates in and around the reactor facility are achieved when the primary reactor water is removed or drained. A LOCA would be a scenario where the dose to workers and the public would be maximized.

Dose to workers and the public must not exceed limits set by the NRC for licensed activities. Regulations in 10 CFR 20 dictate dose limits allowable for radiation workers and members of the public from licensed activities. The dose to the public at facility boundaries should be less than 100 mrem in a year or 2 mrem in any one hour [1]. Modeling the OSTR with MCNP5 allows dose rates to be estimated in the event of a LOCA and benchmarked against values calculated in the OSTR SAR. The research will show that the dose rates are likely less than previously determined in the OSTR SAR.

1.2 TRIGA® Reactors

The TRIGA® (Testing, Research, Isotope, General Atomics) reactor provides an invaluable tool for nuclear engineering and radiation health physics students to study and evaluate nuclear processes. The reactor is situated toward the western edge of the OSU campus in Corvallis, Oregon. The reactor is licensed by the Nuclear Regulatory Commission (NRC) to operate up to 1.1 MW, and contains low enriched uranium (LEU) fuel.

Nuclear reactor operation safety is an issue that arose before the very first nuclear reactor, the Chicago Pile, became critical on December 2nd, 1942 [2]. Since then, the need for scientists to have a tool to help understand a nuclear chain reaction and reactor control has increased considerably. Prior to the development of research

reactors training for operators and scientists was very theoretical, with rare chances for practical training. This need resulted in the development of a small, low power reactor "that is safe even in the hands of a young graduate student" [3] – the TRIGA® reactor.

A negative public perception of nuclear power, and radiation in general, requires the nuclear industry to be as faultless as possible in designs and operation. The inherent safety in the TRIGA® design removes some error associated with human intervention, and allows the reactor to power down in the event of mechanical system failure [4]. TRIGA® inherent safety is accomplished with a fuel design in which negative feedback occurs in the reactivity as temperature increases to safely shutdown the reactor.

1.2.1 TRIGA® Background

TRIGA® reactors were developed by General Atomics as one of their initiatives to create peaceful uses for nuclear technology. The original TRIGA® Mark I was designed with graphite reflected core located in an open tank of water which was all placed underground. The OSTR is a Mark II version. The Mark II is similar to the Mark I in design except the water tank and core sit above ground and is surrounded by a concrete bioshield.

The core of the reactor sits below approximately 16 feet of water. Surrounding the core is an 8 inch graphite reflector also containing 2 inches of lead. Approximately 12 inches of water is followed by approximately 8 feet of the cement bioshield. The core consists of 87 LEU Uranium/Zirconium hydride fuel elements and 4 control rods in a circular grid array. Each fuel element has graphite reflectors at each end, and is surrounded by stainless steel cladding. The reactor operates at 1.1 MW, and can pulse up to approximately 2,000 MW [5]. Figure 1 shows a side view of OSTR.

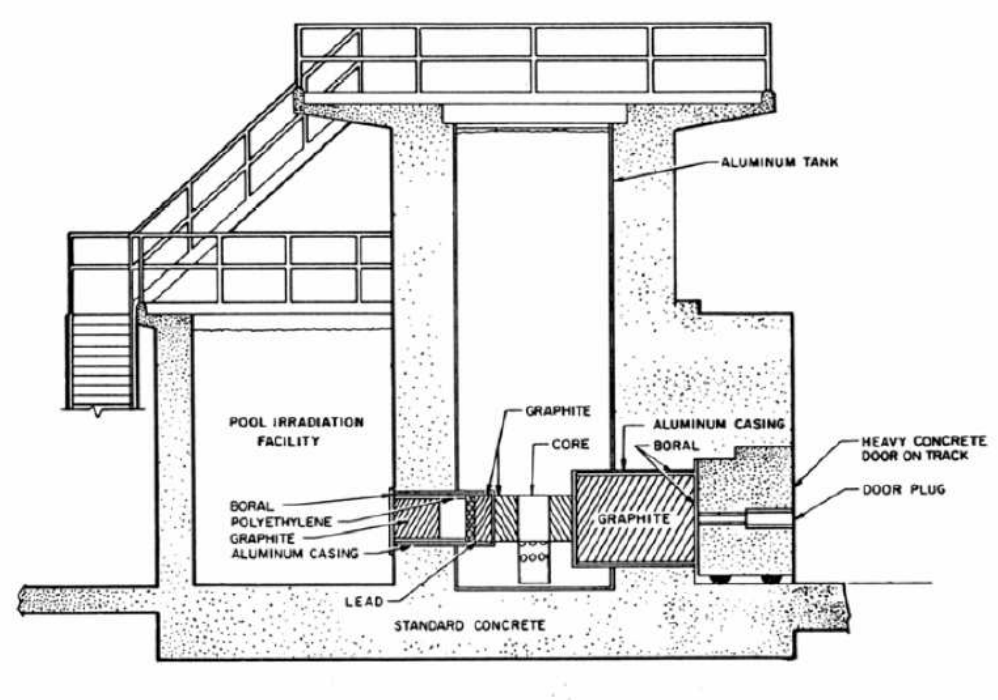

Figure 1. Side View of a TRIGA® Mark II reactor [6].

1.2.2 TRIGA® Fuel Design

The fuel elements in the OSTR are composed of low enriched uranium in a zirconium hydride matrix. The fuel also includes a burnable poison, erbium. The erbium has a double resonance at approximately 0.5 eV. As the fuel temperature increases, the resonance cross section appears to spread out and cover a wider range of energy [7]. As the temperature and resonance increase, thermal flux is depressed and the net reactivity decreases. This process is called Doppler broadening and is useful for adding stability to core reactivity.

Reactivity, an indicator of how many neutrons are available for fission within a reactor core, is defined as:

$$\rho = [k(t) - 1]/k(t) \qquad \textbf{Equation 1.}$$

where k is the time dependent multiplication factor [7]. If reactivity is less than zero, the core is subcritical and there are fewer neutrons in the following generation than the

previous. If reactivity is zero, there is one neutron produced from fission for every neutron in the previous generation and the reactor is critical. If reactivity is greater than zero, each neutron produces more than one neutron by fission and the reactor is supercritical. The amount of change in reactivity per change in degree of fuel temperature is the reactivity temperature coefficient:

$$\alpha = \frac{(\delta p/\delta T)}{p} \qquad \textbf{Equation 2.}$$

where p is the reactivity and T is the temperature. Reactors are required by the general design criterion of the Nuclear Regulatory Commission (NRC) to utilize a negative temperature coefficient within the power operating range [8].

The effect of the negative coefficient is that as the fuel heats up, the number of neutrons produced from each generation is reduced. The inherently safe design attained with a negative temperature coefficient is achieved by use of hydrogen moderator and erbium poison integrated within the fuel elements of TRIGA® reactors. In TRIGA ® reactors the negative temperature coefficient of the fuel will prevent further temperature increasing and ultimate meltdown. Although a LOCA will not result in fuel melting, the core would be uncovered creating a significant source term.

2. Literature Review

An analysis of the dose rate produced above the core as a result of a LOCA was performed in the OSTR SAR [9]. Two scenarios for LOCA were considered: 1) water pumped from the reactor tank and 2) reactor tank failure. The final determination was that the pump configuration for the OSTR could not result in complete loss of water from the tank. The water pump return pipe is above the top of the reactor core and will not drain water below the level of the reactor core. Thus, a reactor tank failure would be the main consideration for a LOCA.

Reactor tank failure could be caused by corrosion or mechanical failure of a joint on the reactor or an attached piping system. However, in the case of corrosion, the

leaks would be noticeable, and would undergo timely repair or an addition of water to the system to compensate for primary water loss. Mechanical failure could lead to extreme and irreversible loss of primary coolant from the reactor core. This could be caused by a sizeable object falling into the tank and irreparably damaging the tank wall, or the remote possibility of structural damage caused by and earthquake.

Once the core is uncovered there are two items that must be analyzed. The first is that the core will remain subcritical. Second is that dose rates in and around the facility do not exceed 10 CFR 20 regulations. The focus of this work is to estimate the source term and the resulting dose rates at points external to the reactor building in the event of an uncovered core.

The OSTR SAR utilized the activity equation from LaMarsh [10], equation 7, to determine the activity present in the core as a function of time after shutdown. The limitations of this equation are that it only applies to one fuel pin, and it only takes into account one operating cycle. If the reactor has been cycled on and off, long lived fission product buildup may skew the source activity. In the analysis the source was modeled as a cylinder, and the total activity was divided by the volume of the cylinder to determine the source flux. The fission product activity and source strength as calculated in the SAR are shown in Table 1.

Table 1. Fission Product Activity and Source Flux After Shutdown from the OSTR SAR.

Time After Shutdown	Fission Product Activity (Ci)	Flux/Core Height ($\gamma/cm^3 sec$)
10 seconds	8.15E+06	5.11E+12
1 hour	1.24E+06	7.78E+11
1 day	9.70E+05	6.08E+11
1 week	5.20E+05	3.26E+11
1 month	2.86E+05	1.79E+11

Once the source strength was determined, the dose rate at the reactor top was calculated using Equation 3:

$$\Phi = [S_v R^2/4\mu_c a^2][1-\exp(-\mu_c h)\ ] \qquad \textbf{Equation 3.}$$

where Φ is $\gamma\ cm^{-2}\ sec^{-1}$, S_v is the source flux per core height in $\gamma\ cm^{-3}\ sec^{-1}$, R is the core radius in cm, μ_c is the core attenuation coefficient ($1/cm^{-1}$), and h is the core height. Once the photon flux was calculated in $\gamma\ cm^{-2}\ sec^{-1}$, a dose conversion factor of $4.6x10^{-12}$ Sv $cm^2\ \gamma^{-1}$ was used to convert the flux to an effective dose equivalent rate. Table 2 shows the effective dose rates calculated in the OSTR SAR at the top of the cement bioshield. This methodology has also been used at other research reactor facilities [11].

Table 2. Effective Dose Rates at Reactor Top after Shutdown from the OSTR SAR.

Time After Shutdown	Effective Dose Equivalent Rate (rem/hr)
10 seconds	1.00E+04
1 hour	1.52E+03
1 day	1.19E+03
1 week	6.39E+02
1 month	3.51E+02

The following analysis will compare effective dose equivalent rates determined with MCNP5 analysis to the effective dose equivalent rates from the SAR.

An article by Patton H McGinley [12] examines dose rates calculated using equations from the National Council on Radiation Protection and Measurements (NCRP) Report # 51 [13]. The article compares photon and neutron measured dose rates at an 18 MeV medical accelerator with those calculated using equations from the NCRP Report #51. According to McGinley, the equations overestimate the photon dose rates up to approximately 10 meters. At distances greater than 10 meters, the calculated photon dose rates are underestimated. According to the data presented in the McGinley article, a correction factor would need to be determined for the facility before relying strictly on NCRP equations to determine dose rates external to the OSTR.

3. Background Theory

3.1 Fission Theory

Fission events produce fission fragments, neutrons, gamma rays and neutrinos. The fission fragments are charged particles since the fission process removes some of the electrons from the outer shells. The charged particles interact quickly within their surroundings, ionizing the atoms of the medium and losing energy. The neutrons, gamma rays and neutrinos are neutral in charge but behave differently. Neutral particles will travel in a straight trajectory until they collide with another particle. At this point they either are scattered or absorbed [7].

Neutrons are born with a distribution of energies, with an average energy of approximately 2 MeV, and may be characterized by their kinetic energy value. Neutron energies can be classified into three different neutron energies: fast, epithermal and thermal. Other energy ranges are defined, but fit within these three categories. Fast neutrons have an energy range from 0.01 to 10 MeV and their distribution, $\chi(E)$, is represented by Equation 5 [7]:

$$\chi(E)=0.453\exp(-1.036E)\sinh((2.29E)^{1/2}) \qquad \textbf{Equation 5.}$$

where E is the energy in eV. The epithermal neutron energy range is approximately 1 to 10 keV, whereas thermal neutrons have energies less than 1 eV. Thermal neutron energy distribution is ideally characterized by the Maxwell-Boltzmann equation:

$$M(E)=\frac{2*\pi*E^{1/2}}{(\pi kT)^{3/2}}\exp(-E/kT) \qquad \textbf{Equation 6.}$$

where E is the energy in eV, T is the temperature in K, and k is the Boltzmann Constant of $8.617\text{x}10^{-5}$ eV/K [7]. The energy ranges presented here are not definite values and may vary depending upon the definition.

In the case of the TRIGA reactor at OSU, the neutrons produced are moderated by the uranium hydride fuel and the primary coolant. Thermalized neutrons that diffuse in the core or re-enter the core from the primary coolant may go on to produce fission within the fuel.

During fissioning, the target nucleus will split into two different nuclei. When a thermal neutron causes fission, there is a well defined difference between the masses of the two newly created nuclei. If the neutron energy is greater than a few eV, the nuclei may split where the mass is distributed more equally. Figure 2 below depicts the dip in the fission yield curve for thermal energies, and the flattening of the curve for higher energy neutrons.

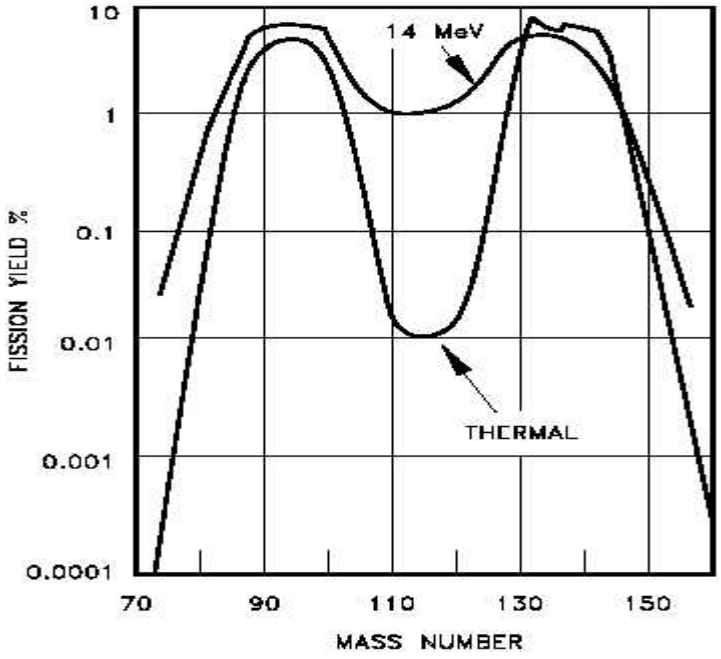

Figure 2. Uranium 235 Fission yield vs. mass number [14].

Lower atomic number isotopes have a neutron to proton ratio of 1:1. As atomic number increases, the isotopes reach stability with a higher number of neutrons than protons. Shown in Figure 3, the fission fragments created from fission typically do not have a stable ratio of neutrons to protons; therefore they will decay to reach the line of stability.

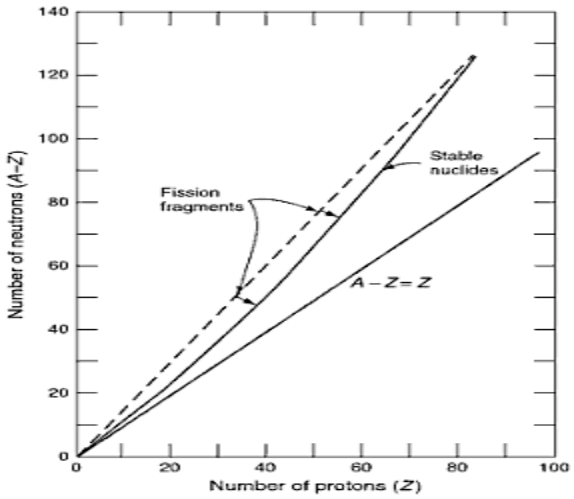

Figure 3. Fission fragment instability diagram [9].

Each daughter product of the fission fragment decay has a different decay half life. Thus, the time required to reach stability is different for each isotope created through fission [7].

3.2 Fission Product Decay Activity

The activity in curies produced by the decay products may be calculated by the following:

$$A(t)= 1.4x10^{6} P[t^{-0.2} – (t+T)^{-0.2}] \qquad \textbf{Equation 7.}$$

where P is the reactor thermal power (MW), t is the time after shutdown in days, and T is the operating time prior to shutdown [10].

The OSTR operates approximately 7 hours per weekday at 1 MW power. Plotting Equation 7 versus time with a 7 hour reactor operating time gives the decay shown in Figure 4.

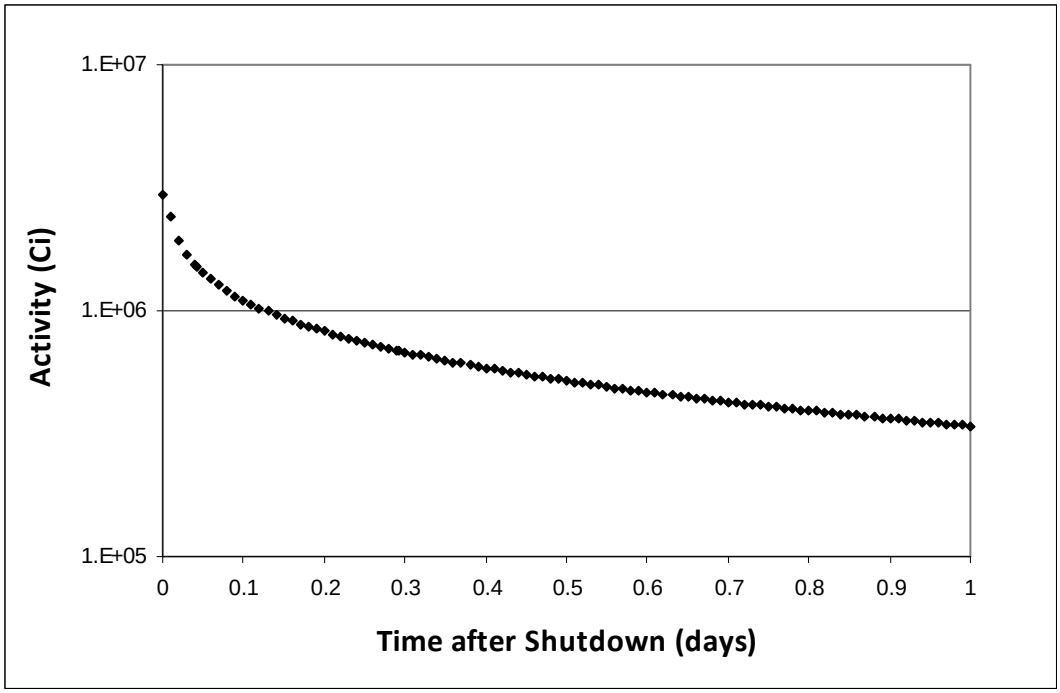

Figure 4. Fission product activity as a function of time after OSTR shutdown.

Using equation 7 with a 7 hour operating time the activity of the OSTR core is calculated to be 1.79 MCi at end of bombardment (EOB). During shut down the fission products decay, but longer lived isotopes do not completely dissipate. The next operating cycle adds to the amount of longer half life isotopes produced. The decay activity resulting from these longer lived isotopes causes a shift in the plot to a higher activity value than one would see if a reactor was shut down after constant operation.

3.3 Electromagnetic Radiation

Photons are the quantum of energy which comprises electromagnetic radiation (EMR) [15]. Photons have no mass, no charge, and travel at the speed of light. EMR classification depends upon the wavelength and frequency of the wave generated. Figure 5 shows the range of EMR and classification as a function of wavelength.

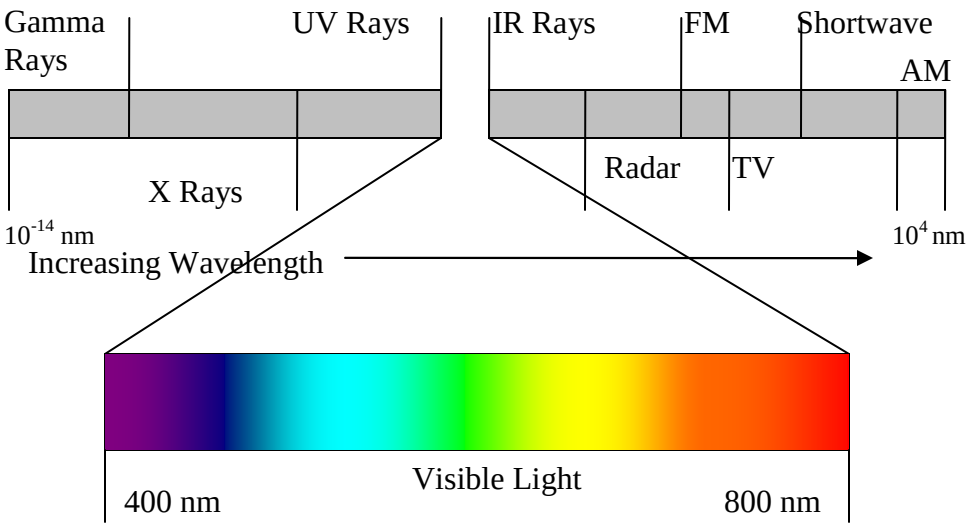

Figure 5. Electromagnetic energy spectrum.

Photon energies are inversely proportional to their wavelength. The relationship between energy and wavelength is given by:

$$E=hc/\lambda \qquad \textbf{Equation 8.}$$

where h is Planck's constant, c is the speed of light, and λ is the wavelength.

Photons interact with the medium by absorption and scatter. Once photons have traveled through a medium, scattering may result in photons of a different energy or a different angle than the original photon beam [15]. Photons may travel a long distance in a medium before interacting, so they are the primary concern for estimating dose from uncovering of the OSTR. Photon interaction mechanisms are discussed further in the next section.

3.4 Shielding and Photon Interactions

The water surrounding the OSTR reactor core provides shielding for the emitted radiation, cooling for the reactor core and neutron moderation. Radiation traveling through a medium undergoes either geometric or material attenuation. Geometric

attenuation occurs when a given number of particles disperse into a larger volume of medium. Material attenuation occurs when the photons are absorbed from the incident photon beam, or scatter in a direction away from that of the incident photon beam [15].

To accurately describe the total attenuation through a material, both material and geometric attenuation must be taken into account. Once the photons have been scattered, they will enter a detector at an angle different from the initial beam angle or be scattered away from a detector. Radiation flux decreases in a material exponentially according to Equation 9:

$$I(x)=I(0)Be^{-\mu x} \qquad \textbf{Equation 9.}$$

where I is the flux, B is the buildup factor, μ is the linear attenuation coefficient and x is the distance the photon travels through the medium. The buildup factor is a correction factor based on the thickness and energy of the photons interacting with in a material. The correction factor takes into account photons that are scattered back toward the detector but are not taken into account by use of the linear attenuation coefficient alone.

3.4.1 Photoelectric Effect

Photoelectric effect occurs when a photon transfers sufficient energy to an inner shell electron, thus ejecting the electron from the atom [15]. The kinetic energy of the electron is equal to the energy of the incident photon minus the electron binding energy:

$$T = E_\gamma - B_e \qquad \textbf{Equation 10.}$$

where E_γ is the energy of the incident photon and B_e is the binding energy [16]. The probability of the photoelectric effect increases with increasing atomic number, Z, and with lower energy photons. Typically the photons that undergo this type of interaction are less than 0.5 MeV.

3.4.2 Pair Production

Pair production occurs when a photon traversing a high electromagnetic field is converted into an electron positron pair. The energy of the incident photon must exceed 1.022 MeV to provide the rest mass energy of the electron and positron. The kinetic energy divided between the remaining electron and positron pair is:

$$T_- + T_+ = E_\gamma - 2mc^2 \qquad \textbf{Equation 11.}$$

where $2mc^2$ is 1.022 MeV [16]. The positron electron pair will create ionizations in the surrounding material along their path. The greater the initial energy, the more energy is transferred to the surrounding medium. As the positron slows down, it will become attracted to an electron and will annihilate, producing two 511 keV gamma rays. The resulting gamma rays will continue within the medium, in exactly opposite directions [15].

3.4.3 Compton Scattering

Photons traveling through a medium with loosely bound outer electrons may undergo Compton scattering. The probability of interaction decreases as the photon energy decreases, and increases as the atomic number increases. In Compton scattering, the incoming photon collides with an outer shell electron. The collision transfers part of the photon energy to the electron, and both particles subsequently scatter. The kinetic energy of the electron after collision is dependent upon the initial photon energy and the scatter angle, and is calculated by Equation 12:

$$KE_e = \frac{(h\nu)}{m_o c^2} \cdot \frac{h\nu(1-\cos\theta)}{[1+h\nu/\, m_o c^2\,(1-\cos\theta)]} \qquad \textbf{Equation 12.}$$

The maximum kinetic energy occurs when the scattering angle is 180° [15].

3.4.4 Coherent Scattering

Coherent scattering occurs when the incident photon wavelength is much greater than the radius of the atom or molecules they strike. The result is that the emitted photon will continue to travel at the same energy as before the collision. Coherent scattering differs from the previously mentioned types of scattering in that it: 1) does not result in a different particle emitted from the atom and 2) results in retention of all energy by the incident photon.

3.5 Ionization Chambers

An ion chamber is a type of detector that depends upon interactions within a gas medium to create ion pairs. Ion pairs are created as the radiation interacts within the gas by depositing energy and ionizing the atoms. The minimum amount of energy required to remove an electron from its shell ranges from 10 to 25 eV depending on the type of gas; however, not all energy deposited by the radiation results in the removal of an electron from its shell.

There are several factors that can reduce the number of ion pairs formed within the gas, including recombination and electron attachment. Recombination occurs when positive and negative ions join together to create neutral atoms. Electron attachment effectively reduces the number of free electrons in the ion chamber. As the electrons diffuse through the gas, a high electron affinity gas may attract electrons to a neutral atom. The result is an increase in negative ions within the gas.

To overcome the overall reduction in ion pairs, an electric field is applied to the ion chamber. The field induces separation of the negatively and positively charged particles. The oppositely charged particles migrate to electrodes, creating a current in the detector. The magnitude of the current produced is proportional to the number of ion pairs that are formed from ionization of the gas.

To account for the average energy lost to events that do not result in ion pairs, W-values were created. The W-value is a correction factor that takes into account the

type of radiation and the chamber gas. Knowing the W-value for the specified ion chamber gas and type of radiation, the energy of incident radiation can determined from the number of ion pairs formed [17].

3.6 Dose and Dose Equivalent

Absorbed dose is the amount of energy from ionizing radiation deposited in a given medium [15]. The units of absorbed dose are rad, or gray in SI units. The absorbed dose is converted to dose equivalent in units of rem, or sieverts in SI units, by a quality factor. The quality factor takes into account the effectiveness of the radiation as compared to a standard low LET radiation.

For this research, the exposure values measured at distances above the reactor core are a starting point to calculate the dose rate. The exposure can either be measured with a detector or estimated using analytical methods. Once the exposure is determined, it is converted to rad by Equation 13:

$$1\ R = 0.877\ \text{rad (in air)} = D\ \text{(absorbed dose)} \qquad \textbf{Equation 13.}$$

where R is the measured or calculated exposure. A rad is the equivalent to 100 ergs of energy absorbed in 1 gram of absorbing medium [15].

The amount of biological damage incurred from radiation depends upon the type of incident radiation. Radiation that has a high linear energy transfer (LET) will do more damage than radiation with a low LET. A high LET radiation will deposit more energy over a given linear amount of tissue than a low LET radiation. To account for the differences in energy transfer rates, the absorbed dose is multiplied by a weighting factor to determine the dose equivalent.

$$H = D * Q \qquad \textbf{Equation 14.}$$

where H is the dose equivalent in rem, D is the absorbed dose in rad, and Q is the weighting factor.

To determine the dose rate over a specified amount of time, the activity from equation 7 is integrated to give

$$\int A(t)dt = P\left[\, 1.75E{+}6 \times t^{-.8} - 1.75E{+}6 \times (t+T)^{0.8} \,\right] \qquad \textbf{Equation 15.}$$

where t is the time of interest, and T is the reactor operating time prior to shutdown. The integrated activity is then taken and substituted into equation 18 to give an exposure rate in R/hr. The dose rate is then calculated using equation 13.

3.7 Skyshine

Skyshine occurs when radiation traveling in an upward direction is scattered off of atoms in the atmosphere and travel back toward the earth [18]. In the case of a TRIGA reactor, the core is shielded with sixteen feet of water which attenuates the majority of the radiation produced. However, a LOCA would change the attenuating medium from water to air, significantly reducing the magnitude of the attenuation coefficient. Thus photons traversing a given distance in air would undergo less attenuation than photons traversing the same distance in water.

3.8 MCNP5

MCNP5, Monte Carlo N-Particle, was used to simulate the photon flux from the core and energy deposition in volumes of interest. Monte Carlo methods were originally developed by scientists at Los Alamos National Laboratory during the 1940s [19]. Monte Carlo (MC) methods are mathematically rigorous, and were first made practical for predicting particle transport with the invention of the computer. Computers allowed the multitude of calculations required for MC simulations to be performed in a reasonable time frame. The first version of MCNP was written in 1963, called MCS[18]. Through the years the code was increased in complexity with added particle types and broadening energy value ranges. In the 1970s, eigenvalue algorithms were added to determine k_{eff}.

MCNP simulates particle histories individually from birth to death, terminating each particle upon absorption or exiting the geometry. MCNP allows the user to define the particle transported in a specified geometry. The particle will start in an identified source point, area or volume. The user assigns the particle a given weight and energy. The direction of travel is then randomly selected. To determine the distance a particle travels, the probability of interaction along a given length is calculated by:

$$p(\ell) = \int e^{-\Sigma t \ell} \Sigma_t d\ell \qquad \textbf{Equation 16.}$$

where $p(\ell)$ is the probability of interaction from ℓ to $\ell + d\ell$, and Σ_t is the total cross section. The probability is equal to a random number from zero to 1, ξ. The distance to the next interaction is then given by:

$$\ell = -(1/\Sigma t)*\ln(\xi) \qquad \textbf{Equation 17.}$$

Once the particle interacts, the type of collision is identified. The type of interaction is also determined by random probability based on the absorption, scattering and total cross sections. After the current particle terminates, the next particle is started and a new history is tracked.

The geometry is composed of surfaces and cells, in which surfaces are combined to create cells. The cells are defined by space that has a positive or negative directional relationship to each surface. Once the geometry has been created, the outside universe must be defined as a void. A void is a cell or cells with no material or cross section defined. Once the particle enters the void, the particle is terminated.

4. Materials and Methods

4.1 Exposure Measurements

In order to estimate the activity of the core, exposure measurements were taken using a Technical Associates model CP-MU ion chamber at six different heights above the core [20]. The ion chamber position relative to the core is shown in Figure 6.

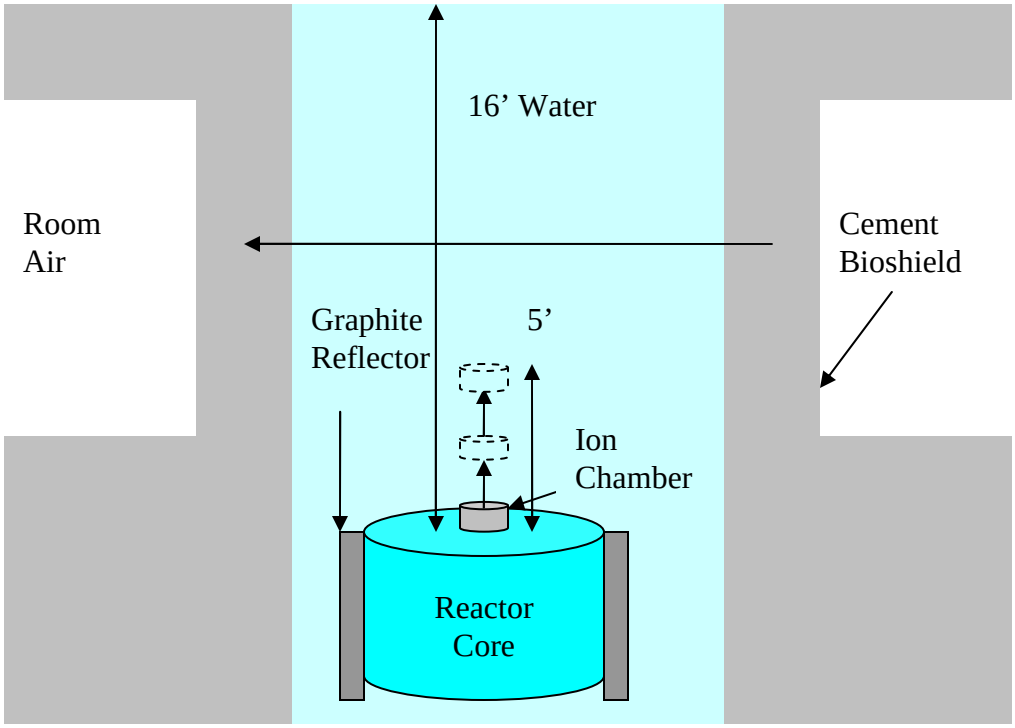

Figure 6. Ion chamber placement above reactor core.

During the measurements, the primary water surrounded the core as removing the water for testing is unfeasible. The results of the exposure measurements at various heights are given in Table 3 [20].

Table 3. Measured exposure rates at points above the OSTR.

Description	Measured Exposure [R/hr]
Top of core	1000 ± 100
1 ft above core	360 ± 100
2 ft above core	72 ± 10
3 ft above core	10 ± 1
4 ft above core	2 ± 0.1
5 ft above core	0.4 ± 0.01

As expected, the measurements show an exponential decrease with distance. To determine the error of each measurement, the minimum ascertainable readout from the ion chamber meter was determined. The range for minimum and maximum values

was then determined by adding and subtracting the minimum measurement reading from the measured value. The measured exposure values were taken in 1999 during a routine survey of the reactor. There was only one set of exposure values taken at the time. Taking measurements to repeat for statistical accuracy would induce error by the measurement technique since the same employee is no longer available to repeat the measurements exactly.

4.2 TRIGA Reactor Modeling

MCNP5 was used to create a simplified model of the OSTR. The model includes the basic geometries of the core, primary coolant, ion chambers, bioshield, surrounding room air, facility building and air above and lateral to the reactor building. A complete MCNP5 input deck is provided in Appendix A.

The core was modeled as a cylindrical volume surrounded by water, cement, and room air. The fine details of the core, such as individual fuel elements and control rods, were not included. The assumptions made for the geometry and source were reasonable since the purpose of the source modeling was to determine a photon distribution and source activity. The ion chamber was modeled as a small cylindrical volume placed at specific heights above the core.

The bioshield and structure support were modeled as three different layers. The bottom layer was modeled as a rectangular base, with a cylinder of core material and water directly in the center. The middle layer is a cylinder of water surrounded by a cylinder of cement. The third layer is similar to the bottom layer with a rectangular shape concrete slab and a cylindrical water center. Figures 7 and 8 are side and top views of the OSTR model.

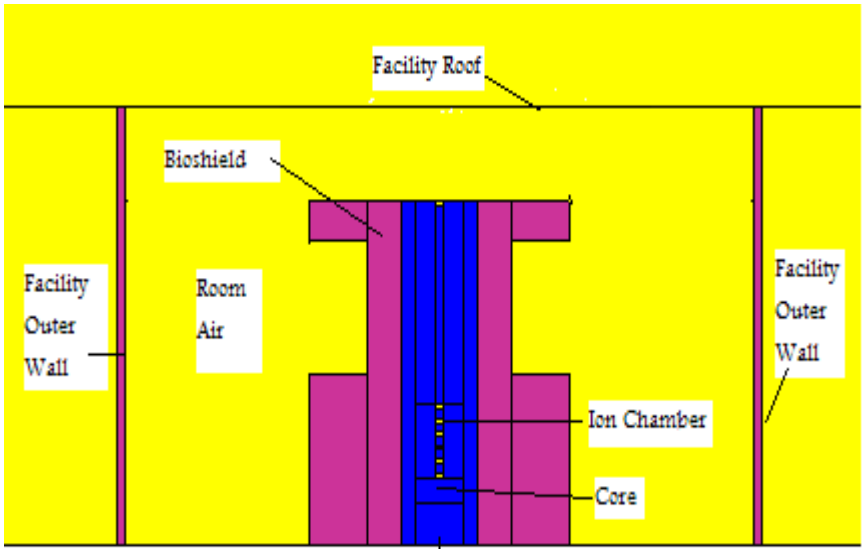

Figure 7. Side Vertical view of the OSTR model.

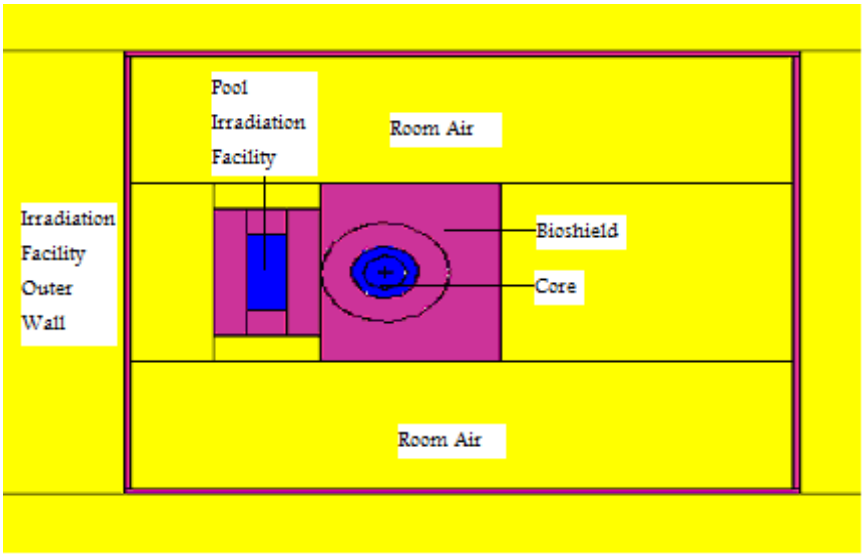

Figure 8. Top view of the OSTR model.

The true octagon shapes of the base and top were modeled as rectangles for ease of modeling. The material thickness of the base, beyond a few inches, is not considered significant since the photons would be attenuated significantly prior to reaching the narrowest width of cement. Also, attenuation from the aluminum housing of the ion chamber was neglected.

4.2.1 Material Specification

The four materials specified for the model of the OSTR and surroundings are given in Table 4.

Table 4. Material compositions for MCNP5 model.

Material Number	Material	Material Component	Atom Percent
1	Cement	Calcium	31.3%
		Oxygen	55.7%
		Silicon	10.1%
		Aluminum	2.2%
		Iron	.7%
2	Water	Hydrogen	66.7%
		Oxygen	33.3%
3	Air	Nitrogen	75%
		Oxygen	25%
4	Stainless Steel (304)	Iron	70%
		Carbon	8%
		Chromium	18%
		Manganese	1%
		Silicon	1%
		Phosphorus	1%
		Sulfur	1%

The air was modeled with nitrogen and oxygen because together they account for greater than 99% of the mass percent of air.

4.2.2 Tally Specification

The tally type used in MCNP5 was a *F8 tally. The F8 tally sums the number of interactions of a certain energy deposited in a cell. The "*" modifier in front of the F8 changes the tally by tracking and summing the energy deposited per initiated particle in the volume of interest [19]. The *F8 tally was chosen because absorbed dose can easily be calculated from the results which are given in units of MeV per initial photon.

Only photon energy deposition is considered important in this analysis. Once the LOCA occurs, the large negative temperature coefficient of the reactor fuel effectively shuts off the fission reactions within the core. Charged particle deposition is ignored since they interact with the surrounding atoms and come to rest after relatively short distances compared to the photons.

4.2.3 Source Specification

Of particular importance is the energy distribution of the photons. The source was modeled as a photon emitting cylinder. Multiple simulations were run with varying initial photon energies for each simulation. The first six simulations were run with monoenergetic photons. The seventh simulation used a Maxwellian distribution and simulations 8 through 13 were run with a distribution of energies from 1 to 10 MeV. The distributions were based on percentages determined from the monoenergetic photon simulations. The distributions are described further in section 5.2. Table 5 lists the energy values used for each simulation.

Table 5. Initial photon energy values for MCNP5 simulations.

Simulation		Energy Values
1	Monoenergetic	1 MeV
2	Monoenergetic	2 MeV
3	Monoenergetic	3 MeV
4	Monoenergetic	5 MeV
5	Monoenergetic	7.5 MeV
6	Monoenergetic	10 MeV
7	Maxwellian	Maxwellian Distribution
8	Distribution 1	Distribution 1 to 10 MeV
9	Distribution 2	Distribution 1 to 10 MeV
10	Distribution 3	Distribution 1 to 10 MeV
11	Distribution 4	Distribution 1 to 10 MeV
12	Distribution 5	Distribution 1 to 10 MeV
13	Distribution 6	Distribution 1 to 10 MeV

5. Results

5.1 Exposure Rates – Monoenergetic Photons

MCNP5 simulations 1 through 6 were run using monoenergetic photon energies, with and without the primary water present. The source activity was calculated with water, based on the energy deposited in the cell positioned directly above the reactor core. The simulation including the primary water was used to determine the source activity because the exposure measurements were taken while the core was surrounded by primary coolant. The activity was then calculated by:

$$A = \frac{E}{[PE*J*100\ rad/Gy]/[.877rad/R*M]} \qquad \textbf{Equation 18.}$$

where A is the activity in photons per hour, E is the exposure in R per hour, PE is the *F8 tally results in MeV per initial photon, J is a MeV to Joules conversion factor of $1.6x10^{-13}$, M is the mass of each cell in kg.

The tally for the cell directly on the core top had the lowest error due to the largest number of particles deposited in the cell. After the core activity was determined using the energy deposited in the cell directly on top of the core, equation 18 was rearranged to solve for E of the remaining cells simulating the ion chamber. Tables 6 and 7 provide the source activity and calculated exposure rates in comparison to the measured exposure rates for simulations 1 through 6, with and without water. Figures 9 and 10 are graphs of exposure rates calculated from the monoenergetic photon energy simulations versus the measured exposure values. The measured values are the same in both graphs; however, the calculated values differ by simulation with or without primary water.

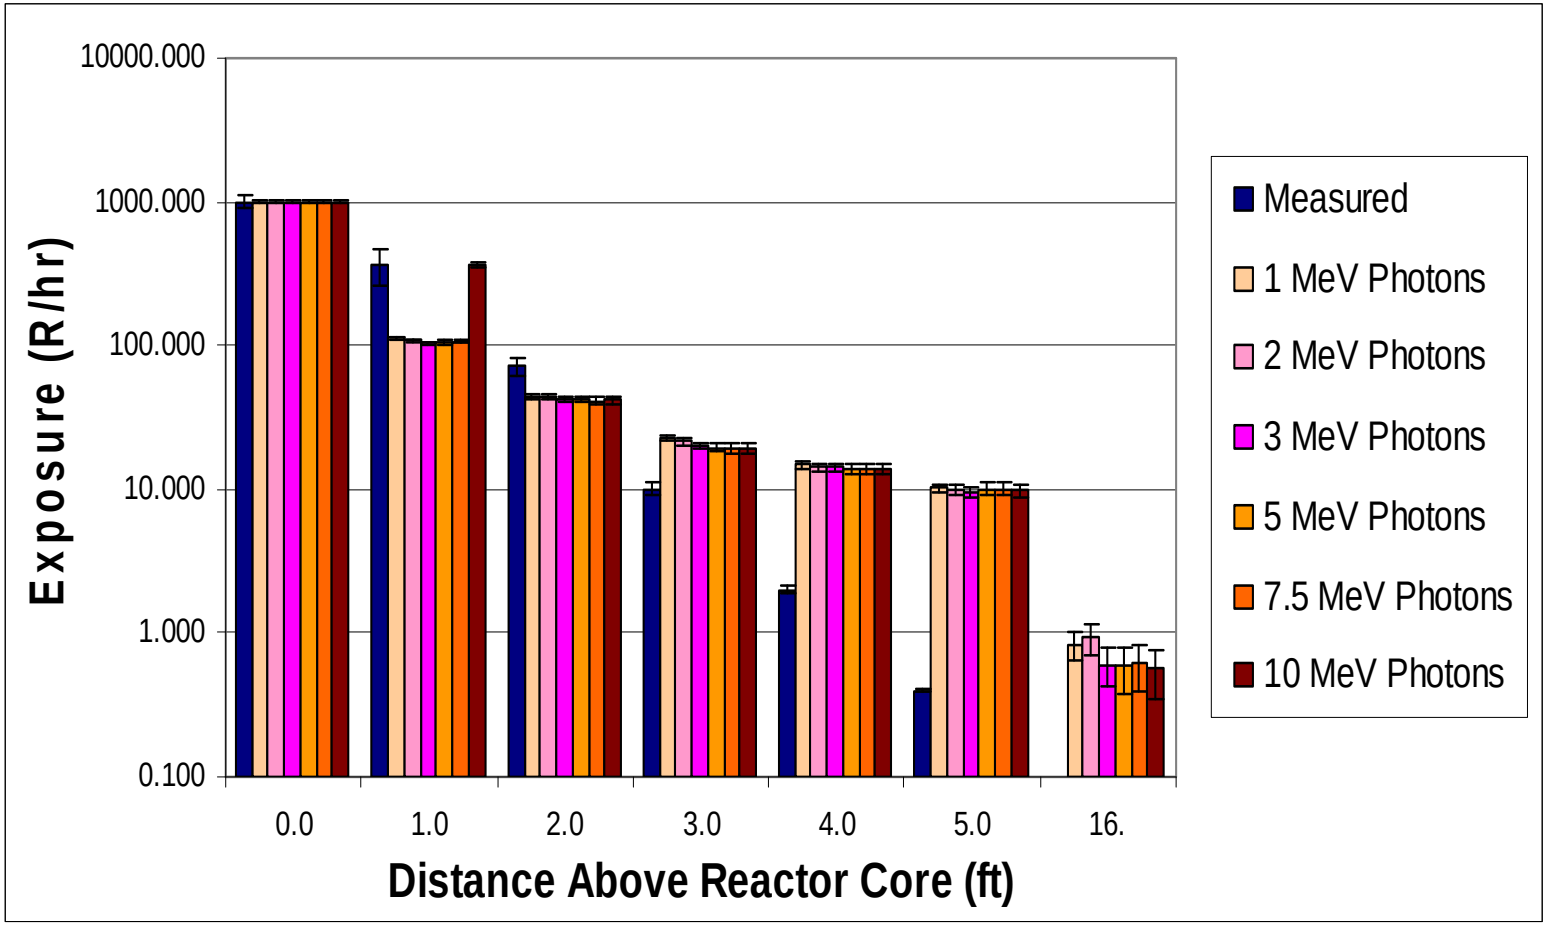

Figure 10. Exposure rates (R/h) at various heights above the TRIGA reactor core in air.

The exposure levels simulated in water did not exceed the measured values. However, the exposure levels in air exceeded measured values as the distance above the core increased. The larger energy deposition in air cells farther from the core occurred because the photons underwent fewer collisions in the air medium, thus retaining greater amounts of their initial energy at greater distances from the core.

The *F8 tally results that would be required to equal the measured exposure values were back calculated using Equation 18. The energies per photon that would equate to the measured exposure values are displayed in Table 8.

Table 8. *F8 tally equivalent to the measured exposure values.

Reactor Top	7.8605E-08	1.1826E-07	1.4299E-07

The *F8 tally results equivalent to the measured exposure rates were then plotted with the MCNP5 simulated *F8 tally results for each monoenergetic photon source. The plots are shown in Figures 11 through 16, below.

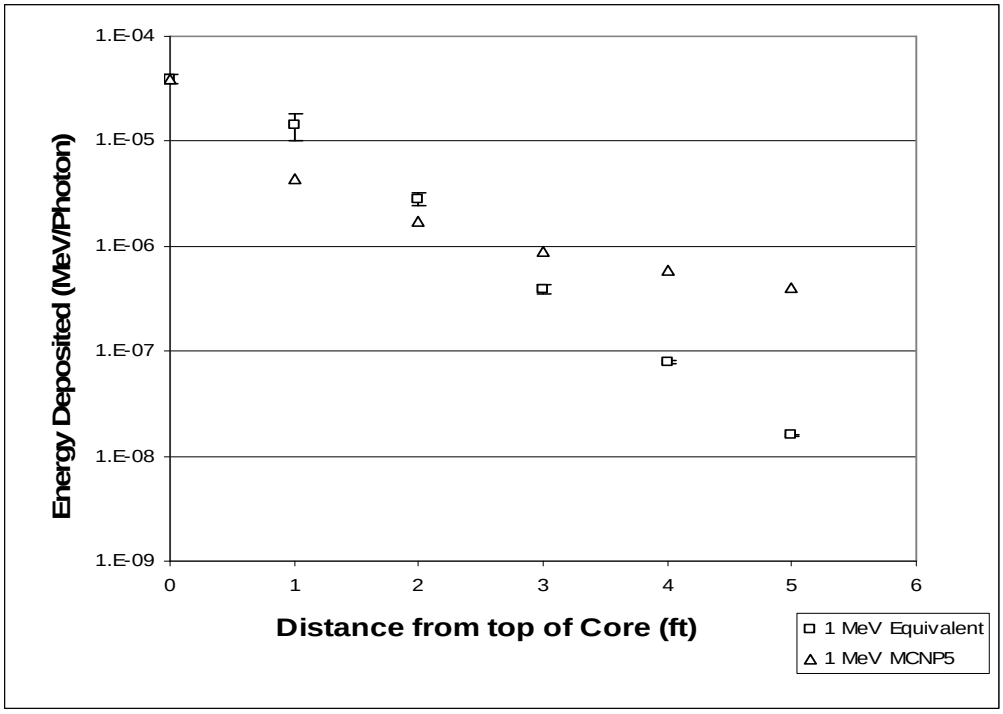

Figure 11. Energy deposited by 1 MeV photons in a simulated ion chamber as a function of distance from the core.

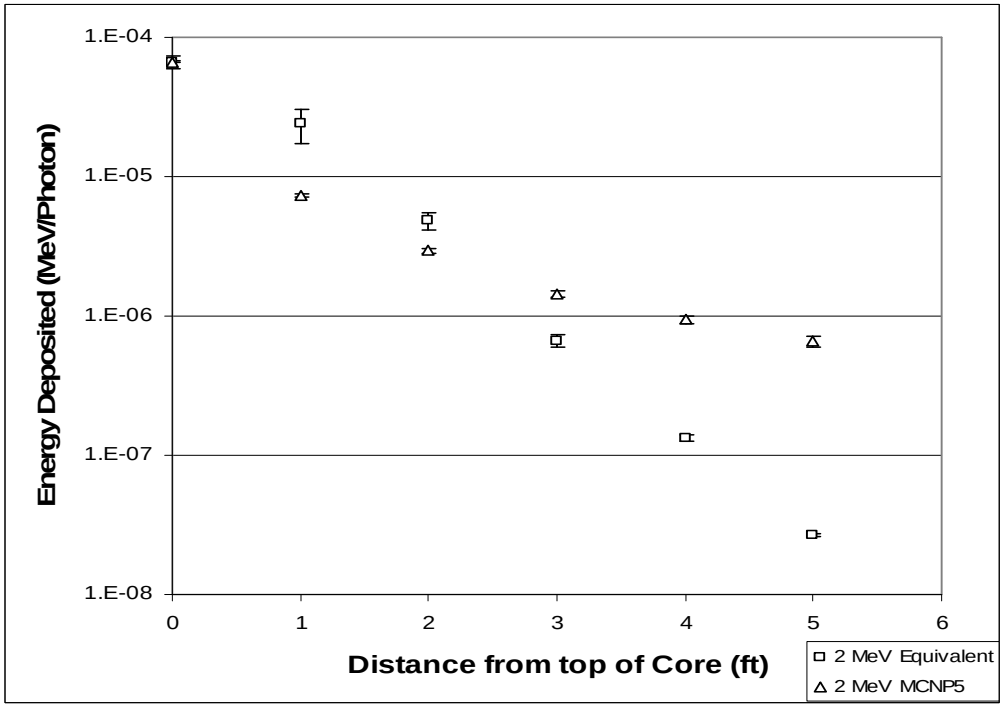

Figure 12. Energy deposited by 2 MeV photons in a simulated ion chamber as a function of distance from the core.

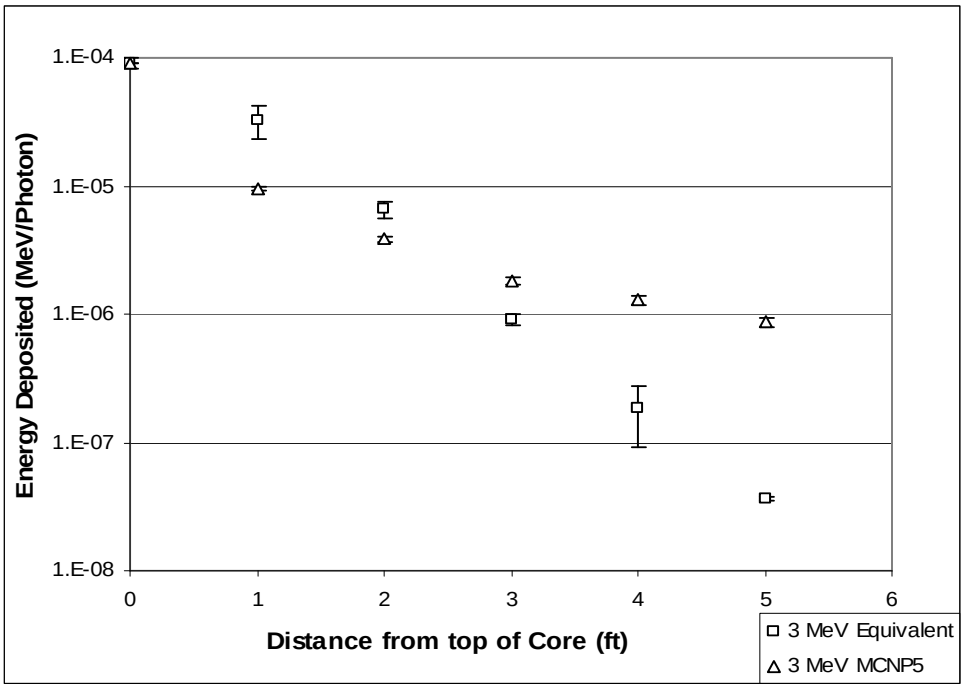

Figure 13. Energy deposited by 3 MeV photons in a simulated ion chamber as a function of distance from the core.

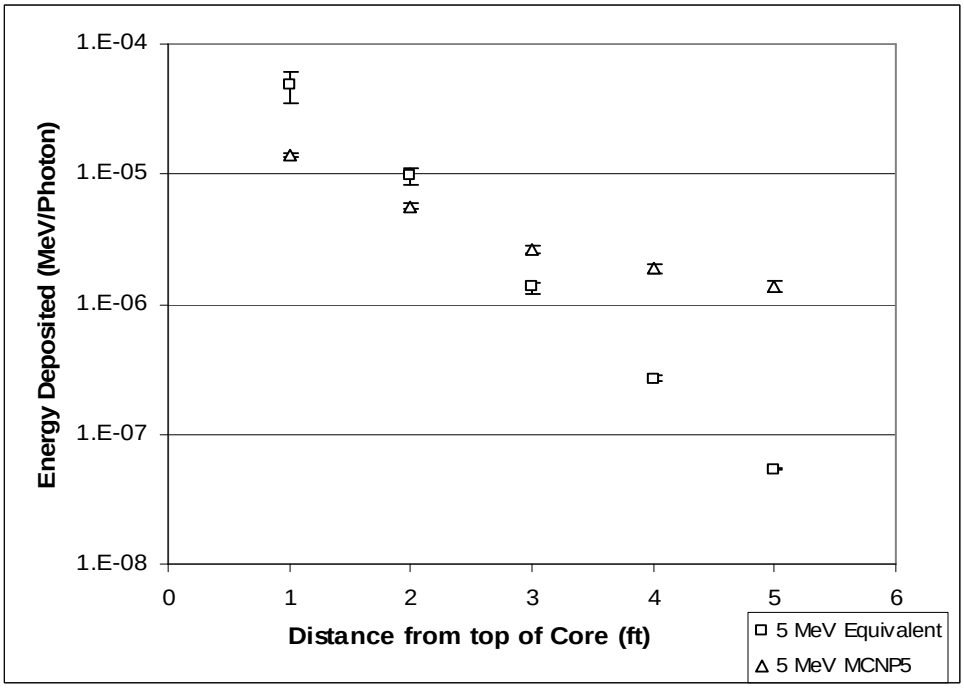

Figure 14. Energy deposited by 5 MeV photons in a simulated ion chamber as a function of distance from the core.

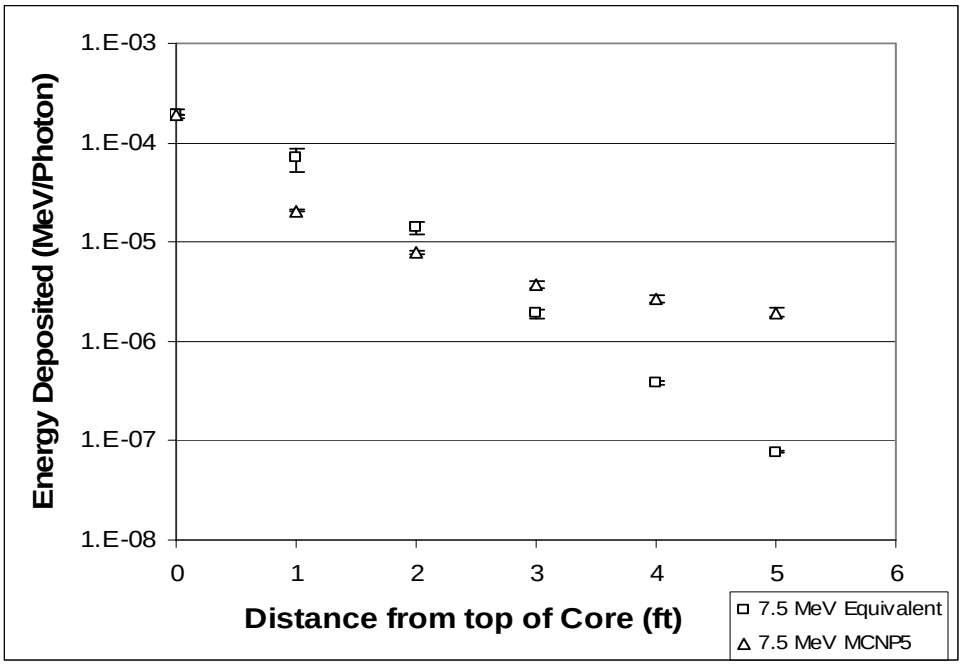

Figure 15. Energy deposited by 5 MeV photons in a simulated ion chamber as a function of distance from the core.

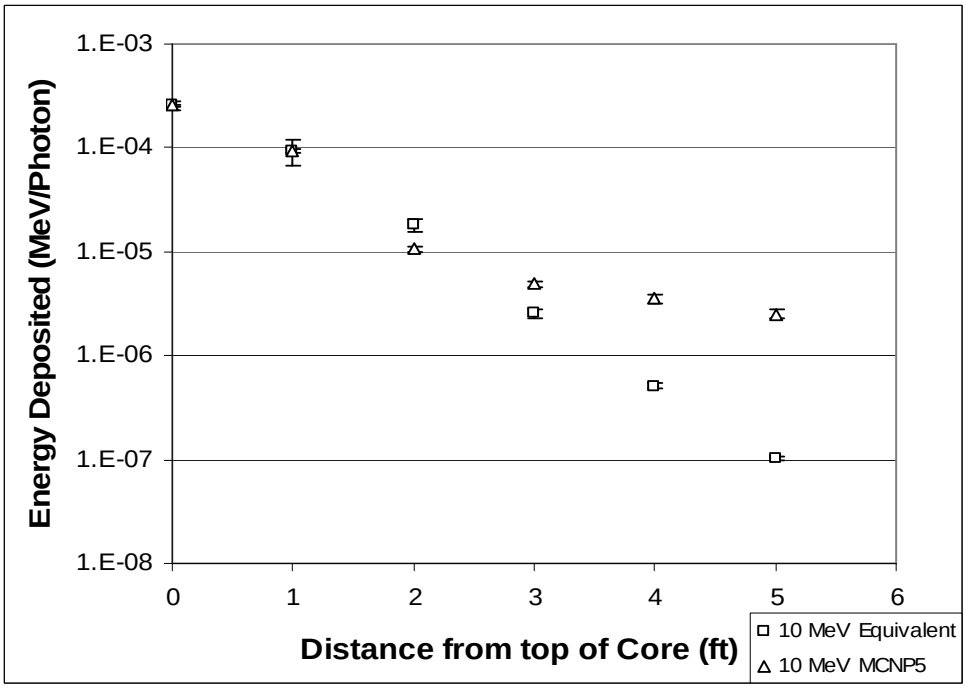

Figure 16. Energy deposited by 10 MeV photons in a simulated ion chamber as a function of distance from the core.

The height at which the plots intersect is approximately 2.7 ft above the core in each case. This height represents the average height required for the number of interactions simulated to be equivalent to the number of interactions equaling the measured exposure values. The number of interactions that occurred in each ion chamber cell was divided by the total number of initiated particles - 300,000,000 for each simulation. The particles interacting in the first, second and third cell, prior to the intersection point, were summed. The percentages of total particles interacting prior to the intersection point were ratioed to 100% and are listed in Table 9.

Table 9. Percent of initial particles to interact prior to intersection point.

MeV	% Particles Between 2' and 3'	% Particles to Reach Intersection	% Particles weighted to 100%
1	0.69	0.0112%	48.71%
2	0.71	0.0083%	36.32%
3	0.75	0.0015%	6.59%
5	0.76	0.0008%	3.64%
7.5	0.77	0.0007%	2.91%
10	0.77	0.0004%	1.83%

The monoenergetic photon energy simulations were only an energy estimation starting point, and it was understood that the photons produced from the core would have a distribution of energies. The percentages listed in Table 9 were determined to help define the photon source spectral shape.

5.2 Exposure Rates – Energy Distributions

The first simulation using an energy distribution, simulation 8, was run with source photon energy percentages as listed in Table 9. The measured exposure values and calculated exposure values of simulation 8 are presented in Table 10.

Table 10. Source activity and calculated exposure of simulation 8.

Position Above Core (ft)	Source Activity (γ/hr)	Calculated Exposure Rate (R/hr)	Measured Exposure Rate (R/hr)
0	4.3211E+16 ± 1.39E+15	1000 ± 100	1000 ± 100
1		180 ± 100	360 ± 100
2		47 ± 10	72 ± 10
3		10.8 ± 1	10 ± 1
4		1.46 ± 0.1	2 ± 0.1
5		0.46 ± 0.01	0.4 ± 0.01
16		0.00 ± 0.01	

A plot of the calculated versus measured exposure with corresponding errors is shown in Figure 17. The exposures rates in the ion chamber positions 3 ft and higher are within the error limits for the measured exposure. Simulations 9 through 11 were then run with varied percentages to attempt a closer match to the measure exposure values. However, simulation 8 most closely matched the measured exposure rates.

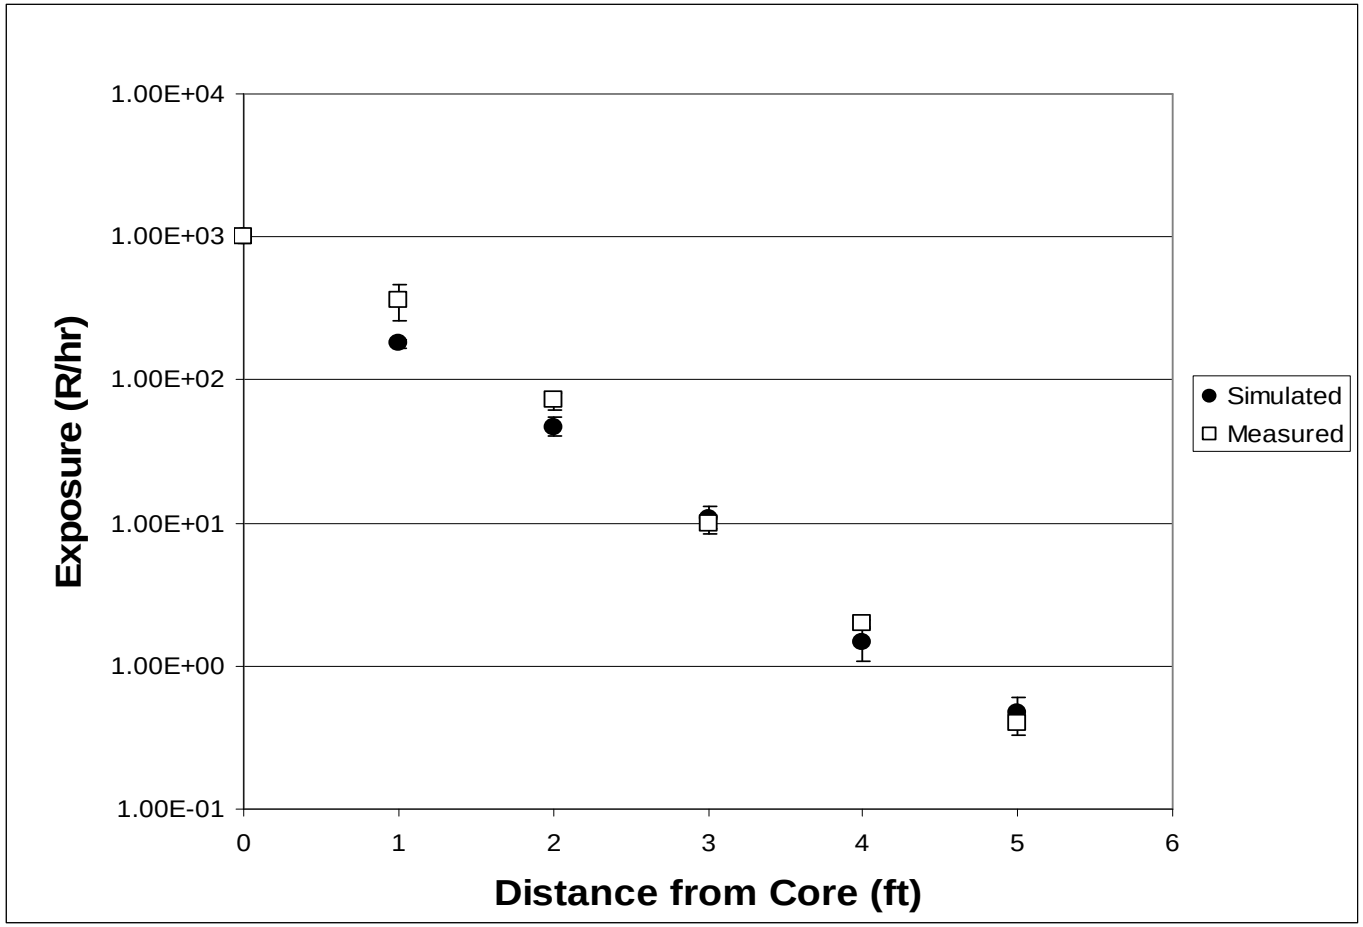

Figure 17. Exposure rates (R/hr) from simulation 8 and measured values at various heights above the TRIGA reactor core.

5.3 Dose Calculation at the Reactor Top

After approximating the photon energy distribution, MCNP5 was run with all primary water surrounding the core removed. Equation 18 was rearranged to solve for the dose rate at the reactor top using the *F8 tally from the MCNP5. The activity was the source activity from simulation 8. The exposure rates as a function of height above the core 7 hours after shutdown are given in Table 11.

Table 11. Simulated exposure levels for a LOCA at positions above the reactor core.

Position	Source Activity (γ/Hour)	R/hr (Calculated)	MCNP Mev/Initial Photon
Top of core	4.3211E+16 ± 1.39E+15	2212 ± 53	1.1078E-05 ± 2.669798E-07
1 ft above core		839 ± 31	4.2002E-06 ± 1.558270E-07
2 ft above core		429 ± 23	2.1492E-06 ± 1.126165E-07
3 ft above core		276 ± 18	1.3812E-06 ± 9.184914E-08
4 ft above core		187 ± 14	9.3516E-07 ± 7.023029E-08
5 ft above core		159 ± 14	7.9514E-07 ± 7.124472E-08
Reactor Top		10 ± 2	5.0351E-08 ± 1.194319E-08

The source activity was then converted to curies and compared to the activity calculated with Equation 7. A plot of the activity versus time is shown in Figure 18. The individual data point is the activity at the reactor top determined from MCNP5 7 hours after shutdown. The time gap of 7 hours was used because the initial exposure measurements were taken 7 hours after the reactor was shutdown. The exposure measurements were taken prior to the beginning of this project, and the gap of 7 hours was outside of the scope of control for this project.

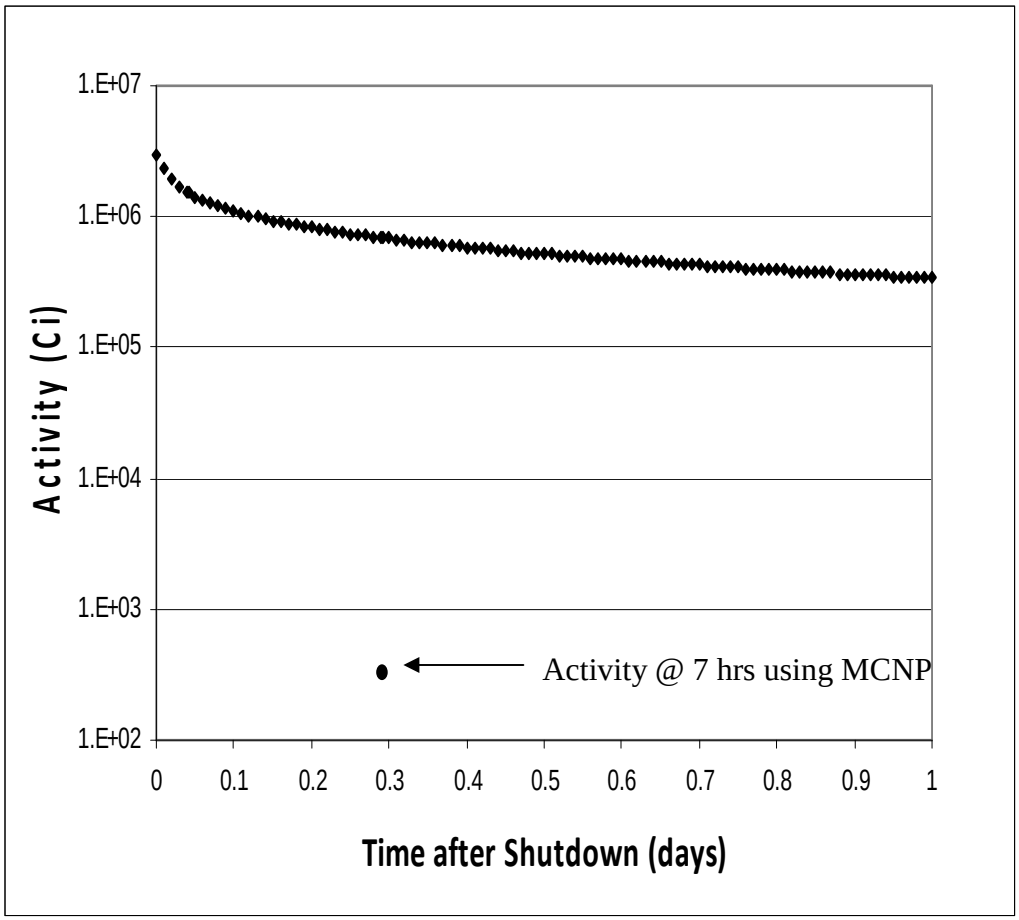

Figure 18. Fission product activity as a function of time after shutdown with activity calculated using Equation 7.

The activity estimated from MCNP5 is less than the activity estimated from core exposure measurements and equation 7. The MCNP5 model significantly underestimates source activity because it only accounted for decays which emitted photons but not other types of emitted radiation. The reactor operating time in equation 7 was adjusted to account for the discrepancy, effectively shifting the curve in Figure 18 so that the individual data point of activity lies on the curve.

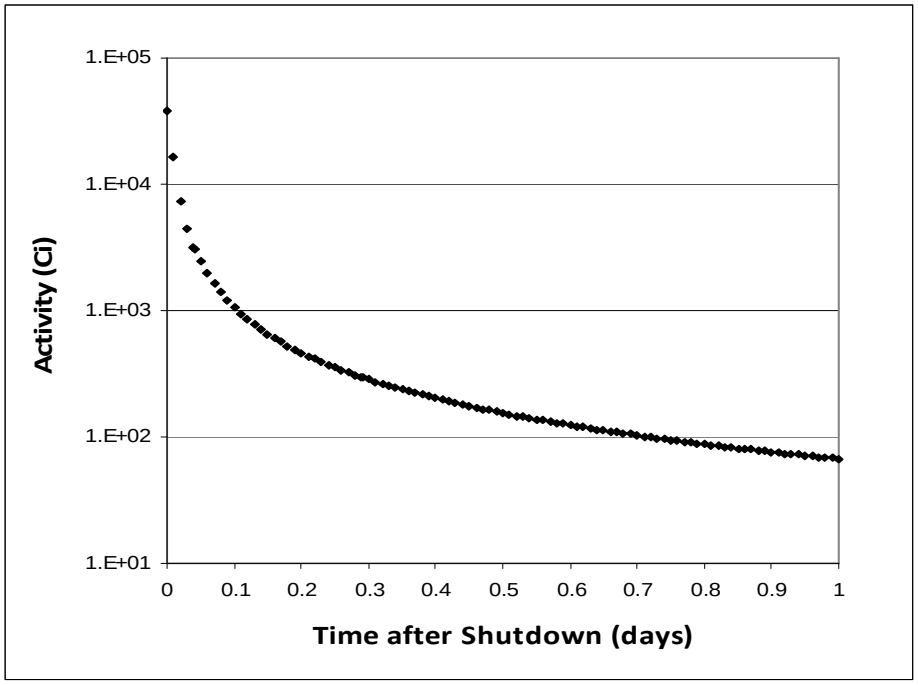

Figure 19. Corrected fission product activity.

At time zero, the activity of the core was estimated at 3.79×10^4 Ci, or 5.05×10^{18} photons per hour. Using this activity, exposure rates were calculated at times after shutdown, and are displayed in Table 12. .

The differences in the activity determined from MCNP5 verses the activity using equation 7 are due to several assumptions used for the equation. First, the MCNP5 model assumes the only radiation energy depositing in the cells is from photons. Equation 7 takes into account radioactive decay produced from all radiation; therefore decays that result in alpha and neutron radiation would be absent from the MCNP5 model. MCNP5 does track the electrons created during the photon interactions and, for the photon only mode, deposits their energy at the point of the photon interaction. Secondly, the TRIGA reactor operation is cyclic with start ups and shutdowns throughout the year on an almost daily basis. The cyclic operation will result in a buildup of longer lived isotopes over a period of time, while

allowing time for the shorter lived isotopes to decay away. This cyclic operation is not accounted for in equation 7.

Using activity values from Figure 19, the exposure was calculated for various times after shutdown. Using equation 13, exposure rate was converted to dose rate and a weighting factor of 1 for photons was used to convert dose rate to dose equivalent rate. The results are compared with the OSTR SAR predicted dose equivalent rates in Table 12.

Table 12. Exposure and dose rates after LOCA at the top of the TRIGA® bioshield.

Time	Source Activity (γ/Hour)	Exposure Rate (R/hr)	Dose Rate (rad/hr)	Dose Equivalent Rate (rem/hr)	Dose Equivalent Rate from SAR (rem/hr)
0	5.055E+18	1031	904	904	1.00E+04
1 hr	4.041E+17	82	72	72	1.52E+03
1 day	8.947E+15	2	2	2	1.19E+03
1 week	8.662E+14	0.18	0.2	0.2	6.39E+02
1 month	1.511E+14	0.03	0.03	0.03	3.51E+02

5.4 Facility External Dose

Dose rates external to the reactor building are given in Figure 20. The figure displays the maximum dose rate, for each 1 meter width increment, on the east side of the reactor building. The range of interest extends from the OSTR east wall up to 60 meters in the horizontal direction. The horizontal blocks, shown in Figure 21, demonstrate an aerial view of the 5 rows of cells that of were modeled from 0 to 100 cm in the z-axis direction (height) east of the reactor facility. Each block contained 60 of the 1 meter in width and height cells.

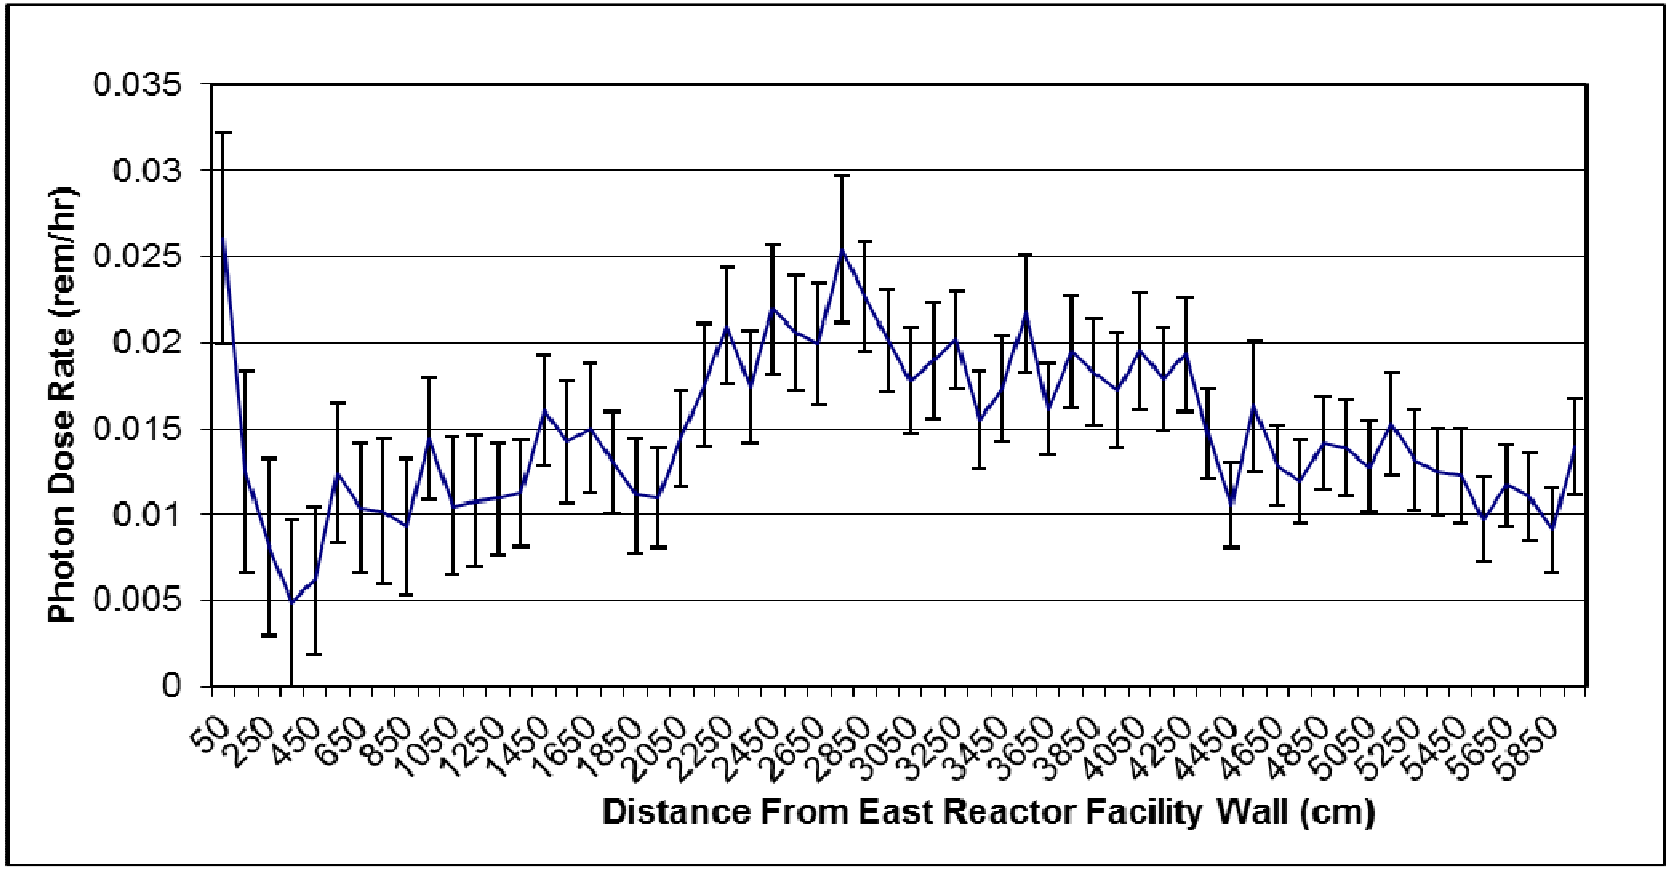

Figure 20. Dose rates external to OSTR from 0 to 100 cm in height.

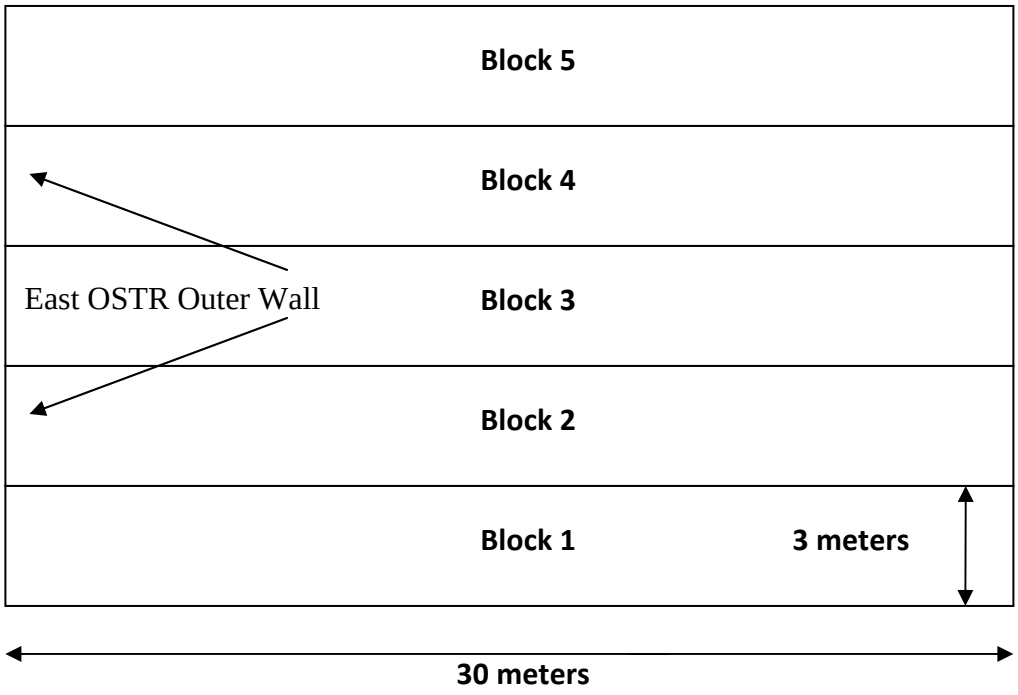

Figure 21. Cell positions for photon dose rates in Figure 19.

Dose rates on the OSTR exterior peak at approximately 30 mrem/hr. The dose rates calculated assume an activity equivalent to the activity present exactly at the end of bombardment.

To determine the dose received within the first hour after a LOCA event, equation 7 was integrated from time 0 hr to time 1 hr after shutdown. The operating time used was 0.00239923 days, which corresponds to the operating time required to match the MCNP5 modeled core activity. The dose within the first hour is 5.33E-3 mrem using the integrated activity from equation 15.

6 Conclusion

This thesis presented an approach to estimate dose rates due to photon skyshine on the exterior of the OSTR building in the event of a LOCA. The findings presented herein indicate that the dose rates of a cell 1 meter in

height may meet the NRC limit of 2 mrem/hr in the event of a LOCA at the OSTR. The dose rates at the reactor top were estimated to be less than the values calculated in the OSTR SAR. However, a direct comparison for the skyshine is not available from the OSTR SAR. The OSTR SAR only takes into account scatter from the reactor building ceiling, and not scatter due to skyshine from the atmosphere above the reactor building. However, the source strength initially used for dose rate calculations would be the same, so one may assume that an overestimation of dose rates at the facility perimeter would also occur.

There are two reasons why the results presented here do not match the OSTR SAR. First, the OSTR SAR assumes that the reactor has been operating continuously for the previous 365 days. This assumption will cause a higher value to be calculated for the activity using equation 7. In reality the reactor operates on a cyclic schedule, and the short lived isotopes have time to decay prior to the next start up. This reduction in short lived isotopes would reduce the activity estimated at shut down, which is consistent with the results obtained from this analysis. Secondly, the SAR assumes only monoenergetic photons of 1 MeV from the source. This is most likely an inaccurate assumption and affects the energy distribution seen at heights above the core.

6.1 Future Work

The analysis presented for this thesis provides validation that the equations used in the OSTR SAR may be overestimating dose rates external to the radiation facility. Future work could involve the determination of a correction factor to be used in conjunction with the methods displayed in the OSTR SAR. A correction factor would provide less conservative, yet likely more accurate dose rates.
