ACKNOWLEDGEMENT

This investigation was made possible through the courtesy of the Western Sulphur Company of San Francisco, California, which has financed a fellowship in the Soils Department of Oregon State Agricultural College for the study of sulfur in relation to soil fertility. The author takes this opportunity to thank Dr. W. L. Powers for helpful council during the execution of this work, and Dr. R. E. Stephenson and Dr. W. V. Halversen for technical suggestions and advice.

STUDIES OF ECONOMIC RATES, FORMS, AND COMBINATIONS OF USE OF SULFUR AS A FERTILIZER

Joseph D. Haynes

INTRODUCTION

Experiments concerning the value of sulfur in agricultural practice have well established the worth of this element for correcting soil alkalinity, bringing bases into solution, controlling certain plant pests and diseases, and, in some sections, supplying a limiting plant food element.

This paper reports experiments dealing with economic means of supplying sulfur where helpful. Extensive reviews of the literature are available (13) and reference will be made only to those researches that are especially pertinent to this investigation.

New forms of commercial sulfur, including a "black gas" sulfur, have recently appeared on the market, the relative value of which has not been established. Before recommendations can be made regarding the use of these products for fertilizer purposes, it is necessary that experiments establish their fertilizer value.

This study was undertaken to throw some light on economic forms, rates, and combinations of sulfur for

fertilizer purposes. With the appearance of different forms of sulfur it was necessary to ascertain the value of these forms and rates to apply per acre, along with promising combinations with gypsum, manure, and lime for increased efficiency or more economic use.

These studies were made on the neutral arid soils and also with soils containing large amounts of black alkali salts.

tion to manufacturers of sulfur and to the farmer who uses this material. The amount and time of application depend much on the rate of oxidation. Manufacturers must know the needs of the farmers so that a sulfur may be manufactured that will give the greatest return for the investment. Rate of sulfur oxidation is important in the field of plant nutrition, because too rapid sulfur oxidation may result in leaching of sulfates, while slow oxidation may fail to meet plant requirements.

HISTORICAL

Sulfur has been used in Oregon as a fertilizer for fifteen years. Powers (12) found sulfur to be as effective as calcium sulfate or potassium sulfate in the Deschutes Valley, and Reimer (15) found that elemental sulfur in acid phosphate, or lime-sulfur spray increased the

yield of alfalfa and legume cover crops in Southern Oregon.

Much of the early experimental work was developed on the theory that sulfur might be a limiting plant food element in certain soils. Increases in yield secured, especially with legume crops, were considered as being due to supplying sulfates. Experimental work by Reimer and Tartar (16) found that sulfur is used by plants as an essential nutrient in increasing the protein. Cystine, one of the amino acids of protein, contains sulfur, which may be a connecting link in the protein series.

Sulfur oxidation depends largely upon two important factors: fineness of division or surface area, as shown by Stephenson (18); and type of soil, according to Halversen and Bollen (6). Materials finer than 40 mesh Stephenson (18) found oxidized at a rate that was adequate to meet plant requirements. Soils containing sand having little buffer action oxidized sulfur more rapidly than heavier soils containing large amounts of clay (6).

Various other activities result in sulfur oxidation. According to Waksman and Joffe (19), Thiobacillus thiooxidans, a sulfur-oxidizing organism, isolated by Lipman and associates, is very active in sulfur oxidation. MacIntire, Gray, and Shaw (11) found that some non-biological oxidation took place in pure quartz, but that

sulfur was not exidized sufficiently to be a means of supplying sulfates for plant growth. Abbott (1) reports that Penicillium luteum exidized 20.3 mg. of sulfur in a period of 20 days. This organism is one of the common molds universally found in soil. Weather and moisture conditions will retard or accelerate exidation. Optimum moisture condition and warm temperature are ideal for sulfur exidation.

For some time gypsum has been advocated for reclamation of "black alkali" soil. Hilgard (7) was among the first to suggest it. Some failures were probably due in part to the reversibility of the reaction of gypsum with the alkali and the low solubility of the gypsum.

$$Na_2^{CO_3} + CaSO_4 \leftrightarrow Na_2^{SO_4} + CaCO_3$$

Sodium Calcium Sodium Calcium carbonate sulfate sulfate carbonate

Lipman (10) suggested sulfur for reclamation of alkali land, the advantage being the non-reversible reaction of the oxidized product as shown below.

Investigations of sulfur as a fertilizer for alfalfa have been conducted in most of the alfalfa producing areas of Oregon and the Northwest. Reclamation experiments in Oregon for alkali land have been centered at Vale. A progress report on this work (14) indicates that the use of a rapid oxidizing sulfur in combination with a legume green manure may prove economical for the reclamation of black alkali land having deep drainage and plentiful irrigation.

Field trials indicate that the state of Oregon has 140,000 acres of good alfalfa land on which the yield may be increased at least one ton more per acre if sulfur were applied. This would mean an increase in hay value of over \$1,000,000 a year with an annual cost of about one dollar per acre, which is less than a dollar per ton for the additional hay. The use of sulfur has contributed to productive value of land in irrigated projects in Oregon.

Extensive fertilizer trials have been conducted on Antelope Clay Adobe soil on the Reimer plats near Medford, Oregon. These trials were started in 1915 and continued for a period of twelve years. Over this period of years alfalfa treated with sulfur has given phenomenal results. For a period of ten years check plats averaged 118 pounds, and the sulfur treated plats averaged 455 pounds from the one-tenth acre plats. This is of particular interest due to the long period of time over which these results were obtained. These trials indicate that sulfur can be used for a period of time

without detrimental effect on the soil, or a decrease in plant growth. In these plats application of a total of 1000 pounds per acre has been used without apparent injury to the land. Also, the increase from this heavy application was no greater than from a lighter one of 100 pounds per acre.

The tendency on the lighter soils is to use a frequent light application of 50 pounds an acre. On the heavy soils such as the Klamath Clay Loam a 100-pound application caused a yearly two-ton increase for a period of five years.

METHODS AND PROCEDURE

To secure information over such a wide range it is necessary to make laboratory and greenhouse studies under controlled conditions and then develop these leads with field studies to check the laboratory and greenhouse work.

The forms of sulfur available for this study
were "gasco," "black gas sulfur," "sand sulfur," and "inoculated sulfur." Gasco is a sulfur by-product of thegas
plant at Portland, Oregon. Black gas sulfur is a byproduct of the gas plant at San Francisco, California.
Sand sulfur is coarsely ground, containing particles
about the size of sand. Inoculated sulfur contains the

sulfur-exidizing organism Thiobacillus thioxidans. Since several of these forms of sulfur are new to the trade it was essential that preliminary tests should be made to make sure that these forms would oxidize and be worth careful investigations.

Having selected those forms of sulfur that showed promise from the preliminary experiments, further studies were planned to compare them, using various rates and combinations in promoting the growth of alfalfa in the greenhouse trials on a soil known to be low in sulfate. These data should serve as an indication of their possible value under field conditions.

For the study of these forms of sulfur in relation to the reclamation of alkali land, laboratory studies on rate of oxidation of different forms of sulfur and percolation trials with sulfur in different combinations were planned to be supplemented by field trials.

The following studies were undertaken:

The rapidity of oxidation of new forms of sulfur in neutral soil; exidation of inoculated and non-inoculated sulfur on neutral and alkali soils; biological changes in soil; greenhouse studies with rates, forms, and combinations of sulfur on neutral soil supplying sulfates as a plant nutrient; flocculation effect of sulfur on soils; neutralization of carbonates and displacement of sodium

on the ultra clay complex with calcium.

Air-dry soil was weighed out in 2-pound amounts, placed in quart mason jars, and mixed with sulfur in different rates and forms, water being added until an optimum moisture condition was reached. This was maintained during the experiment, treatments as shown in Tables 1 and 2. Sulfate determinations were made periodically from 1:5 water extract, and precipitation with a solution of barium chloride was followed by gravimetric determinations. Heavy applications of sulfur were used in order to obtain differences that would be significant.

A medium for determining the number of microorganisms in the soil was made according to Fred and Wakeman (5).

Malheur Clay Loam was employed in this study, 25pound lots being used in each jar as shown in Table 8.
The method used for determining the replaceable bases
in alkali soil was that of Burgess and Breazeale (3),
percolation tests being made over three periods of time,
between which the soil was thoroughly dried. The first
trial was for 252 hours, the second for 396 hours, and
the third for 540 hours. Percolate from each jar was
measured each 38 hours. At the end of each trial, the
total amount of salts removed was determined by analysis
of an aliquot part of the percolate. At the close of

each trial, hydrogen-ion concentration determinations were made with a hydrogen electrode. At the beginning of each trial, the soil was thoroughly mixed to avoid channeling.

Nineteen jars of soil treated with sulfur, lime, and mamure at different rates or in different combinations were used for this experiment. The first twelve jars were filled with Malheur Clay Loam (used by Young) (20), and the last seven jars were of the same type of soil, but having less alkali than the former.

Experiment No. 1

RATE OF OXIDATION OF DIFFERENT FORMS OF SULFUR

Besides studying rate of oxidation of the various sulfurs, another reason for these studies was to find if the small amount of tar present in the black gas sulfur would in any way check oxidation. As sulfur must pass to the sulfate form before it can be used by plants it is necessary to determine with what facility oxidation occurs.

Oxidation studies were undertaken with Deschutes Sandy Loam treated at the rate of 1,000 pounds per acre and tested periodically for this study (Table 1).

Table 1. Rate of Oxidation of Different Forms of Sulfur.

Deschutes Sandy Loam

Treatment :		Period	of I	ncubati	on .	
1,000 lbs. per acre	3 Weeks SO ₄	6 We S04		9 We SO ₄	eks pH	:% oxid- :ized :9 Weeks
Check		•0499	7.2	.0550	7.2	: : 0
Black gas sulfur: (melted & ground):		.1207	6.8	: :.1544:	6.4	: 66.6
Gaseo by-product: (43% S)		.0797	7.1	.0820	7.1	: 41.8
Black gas sulfur: (Colloidal)	• 09 87	.1295	6.3	.1290	6.4	: 49.3
Bac-sul	•0986	.1143	6.5	.1169	6.4	: : 41.2
Sand sulfur	.0330	•0611	7.1	.0964	6.8	: 27.6

Data presented (Table 1) indicate that black gas sulfur oxidizes at a comparatively rapid rate. The small amount of tar present in this material does not seem to interfere with oxidation. The gasco by-product oxidizes at a rate comparable with other commercial forms of sulfur. Sand sulfur oxidizes slowly due to the small surface area exposed.

According to Powers, (13) alfalfa seems to require most sulfate in the early period of growth. During the first six to nine weeks alfalfa takes up most of the sulfates needed; therefore, sulfur should be rapidly oxidized to the sulfate form and available for absorption into the plant in early stages of growth. From data secured it appears that black gas sulfur oxidizes promptly

and should supply sulfate requirements for young alfalfa seedlings as well as later needs.

Experiment No. 2

RATE OF OXIDATION OF SULFUR ON ARID SOILS.

Studies were made with arid soils; namely, Umatilla Medium Sand, Deschutes Sandy Loam, and Malheur Clay Loam. for the purpose of determining the sulfofying power of soils that were neutral, or alkaline in reaction. Of the three soils investigated, the sulfofying power of the alkali soil from Vale, Oregon, was unknown. It was necessary to allow a period of time for sulfur to oxidize before leaching this alkali soil. Under field conditions the sulfur was applied about three months before leaching began. It was undetermined whether this was time enough for the sulfur to oxidize to sulfate. Field trials indicate that sulfur did largely oxidize, but laboratory studies were necessary to determine the rate of oxidation; therefore, an experiment was set up using different rates of sulfur, to determine the amount oxidized, and the changes occurring in hydrogenion concentration.

In Table 2 is presented the amount of sulfates formed after two, four, eight, and sixteen weeks, together with the changes in hydrogen-ion concentrations. Black gas sulfur oxidizes at nearly the same rate as the

inoculated sulfur, except with the highly alkaline soil, Malheur Clay Loam. The inoculated sulfur for the first eight weeks oxidizes more rapidly than the black gas sulfur, after which time the two yield sulfate at a similar rate.

All the soils show a decided change the first four weeks, the pH dropping rapidly and then continuing to remain about the same throughout the remainder of the experiment. The curve for Umatilla Medium Sand shows a steep drop, more so than the other soils. This is due to the low buffer property of this particular soil. The other two soils are finer textured and do not allow such rapid changes in hydrogen-ion concentration.

This trial indicates that sulfur oxidizes well under alkaline conditions, and that the high concentration of salts does not prevent sulfur oxidation. This is also in accord with findings of Kelley and Thomas (8) and Samuels (17), who found that sulfur oxidation is reasonably active in alkaline soils.

From this work it appears that after two months an application of sulfur would oxidize sufficiently so that leaching could take place, as the black gas sulfur at eight weeks was 77.6 per cent oxidized and at the end of sixteen weeks 90.2 per cent oxidized. The tendency appears to be for rapid oxidation the first eight weeks

and then the process slows up, probably due to the sulfuric acid stopping the action of sulfur oxidizing organisms. This is particularly noticeable with the heavy applications.

This application of one ton has neutralized the carbonates present, but probably has had little effect on the exchange of calcium for sodium on the base absorbing complex. One ton of sulfur would not completely reclaim the soil, but should improve it to the extent that crops could be grown.

Leaching intermittently with periods of incubation should be ideal for sulfur oxidation on alkali soils, as the pH would rise with the formation of sodium hydroxide caused by leaching the soil. It appears that one ton of black gas sulfur will neutralize the Malheur Clay Loam employed.

Flocculation With Sulfur-

Figures 5, 6, and 7 show flocculation effect on certain soils; namely Malheur Clay Loam, Umatilla Medium Sand, and Deschutes Sandy Loam. These flocculation photographs were taken at the end of a 16-week incubation period. Treatments are recorded in Table 2.

Soils treated with sulfur were flocculated as represented by the above figures. Checks in all cases remained dark; the treated tubes clearing up. Heavy ap-

plication of sulfur caused flocculation more rapidly than light application, as is shown in figure 7, with gradual clearing of the tubes from left to right.

In the alkali soil flocculation begins as neutrality is approached. Definite flocculation started at pH 7.5. This flocculation, according to Comber, (4) is in part indirect due to bringing some other material into solution which flocculates the soil. The material that is brought into solution in the greatest quantity from application of sulfur, according to Powers, (13) and Larson (9), is calcium. It appears that flocculation from sulfur is due to bringing into solution calcium and possibly some other ions that would tend to flocculate, along with the neutralizing effect from the sulfur.

^{*}B.G.S. Black gas sulfur.

EFFECT OF ALKALI ON MICROFLORA OF SOIL

Soils containing black alkali salts have fewer bacteria than neutral soils, as shown in Table 3. The reproduction of microorganisms is retarded due to unfavorable alkali medium. Application of sulfur to alkaline soil has increased the molds and bacteria due to neutralizing the alkali.

Experiment No. 3 GREENHOUSE TRIALS

Deschutes Experiments

Table 4 and figure 1 represent the results of sulfur on the Yakima Sandy Loam. Three cuttings of hay were secured from these pots and all sulfur treatments increased yield. Leaves from the sulfured plants were greener and larger than from the non-treated. The rate of application of 150 pounds per acre as used in this experiment is a little larger than actual field applications for the soil.

Table 4 with rates, forms, and combinations of sulfur on Deschutes Sandy Loam shows some increases.

Little difference is noted from rates of application

as the 50-pound application appears to give about the same result as obtained with 100 pounds. Four different forms used all gave about the same increase, so it appears that one form of sulfur is as effective as another under the conditions of the experiment. Sulfur usually results in increased yield on this soil, yet little of it is needed. However, this amall amount seems to be essential. The returns from use of sulfur were similar whether used alone or with manure or green manure.

Experiment No. 4 TANK EXPERIMENTS ON ALKALI SOILS.

The tanks filled with alkali soil from Vale experiment field formerly used by Johnston (14) had been stored in the basement since the previously reported leaching tests. These tanks were placed outdoors at Corvallis fully exposed to winter rainfall first of March, 1927. Barley was planted in these tanks the middle of May. The seeds germinated in all these tanks and shoots grew to a length of two or three inches, at which time they turned yellow at the tips and finally died. The exceptions to the above are the tanks shown in figure 4. Increases in straw and grain of the sulfur treated tank over the gysum treated tank and check tank are shown in table 6. Initial reaction of this soil was pH 10.4.

Table 6. Barley Grown on Alkali Soil in Tanks.

	:Yield in grams:		
Treatments	:Grain : Straw	: pH	
Check	0.0 0.0	9.1	
Gypsum 10 T per acre	18.5 6.5	8.5	
Sulfur 1000 lbs. per acre	:31.0 : 12.5	7.8	

These data indicate that sulfur applied at a rate of 1,000 pounds per acre has produced a fair crop of barley on alkali land, when it has been leached with copious amounts of water. The straw from the sulfur treated tank was taller than that grown with gypsum treated and the heads of grain were larger, as shown in figure 4; also sulfur appears to hasten crop maturity.

Hydrogen-ion concentration tests of the three tanks indicate that a pH of 8.5 or above makes it difficult to get barley to mature. It may germinate at a greater alkalinity, yet fail to grow for any length of time. The reaction value should be of the order of pH 8.5 or below if barley is to mature. This is verified by the field trials.

The alkalinity of the gypsum tank increased from pH 7.8 to pH 8.5 between the close of Johnston's work with the tank and the end of present investigation. It appears that the sulfate has reverted to carbonate as reported in the historical section of this paper.

Experiment No. 5

STUDIES WITH SULFUR FOR IMPROVING ALKALI SOILS

The reclamation of black alkali soil is a difficult task due to the "freezing up" after a short period of leaching. According to Breazeale and Burgess (2), this is due to the hydrolysis of the sodium clay complex, sodium carbonate and the hydrated sodium aluminum silicate. All of these compounds will hydrolyze to form sodium hydroxide, which brings about soil disperson. Probably the cation and anion are both concerned in the dispersion, but the cation is believed to be most responsible. As long as there are free sodium ions in solution, the soil will remain dispersed. This means that some chemical should be added to the soil that will neutralize the sodium hydroxide before leaching is continued.

A percolation experiment was set up for the purpose of determining the amount of salts that could be leached from the soil, and to study decrease in hydrogenion concentration and increase in permeability that might occur with exchange of sodium for calcium on the ultra clay complex.

Percolation Experiment

Nineteen jars with different forms, rates, and

combinations of sulfur with other materials were used for this experiment. As indicated in table 8, the first twelve jars were of Malheur Clay Loam used by Young (20). The last seven jars were the same type of soil, but having less alkali than the former.

Percolation experiments were made in three trials. The first trial was for 252 hours, the second for 396 hours, and the third for 540 hours. Water was measured from each jar at regular intervals. At each period the total number of c.c. of percolate were measured from each jar, also at the end of each period the total number of c.c. leached were aggregated, with the total amount of salts removed. At the close of each trial hydrogen-ion determinations were made so that the decrease in pH could be recorded.

Final results show that leaching Jar 5 treated with sulfur at the rate of 2000 lbs. removed a large amount of salts and the alkalinity decreased from pH 10.2 to ph 8.8.

Jar 15 treated with 4000 lbs. of sulfur an acre allowed a rapid percolation compared to check Jar 19. Averaged rate of percolate per hour for the three trials from Jar 15 was 12.7 c.c., and check Jar 19 was 3.7 c.c. The pH decreased on Jar 15 from 9.5 to 8.3, while in check Jar 19 the pH fell only from 9.5 to 9.

From the data for check Jar 1 it appears that leaching with alternate drying removed appreciable quantities of salts, with some lowering of the pH value. Alternate drying and leaching appears to have some advantage in the reclamation of alkali land.

Manure, green manure, gypsum, and lime all decreased the hydrogen-ion concentration to some extent, but the most effective decrease resulted from sulfur.

Jars 14, 15, and 16 treated with applications of 3000, 4000, and 3000 pounds of sulfur an acre have been reclaimed to the extent that some crops could be grown.

Jar 3 containing lime and manure has a tendency to stay open well, but the total salts are not so rapidly removed when compared to the sulfur treated jars.

Jars No. 14 and 16 with 3000 lbs. of sulfur appear to remove the most salts and at the same time remain open fairly well. The heavier application of sulfur on Jar 15 gives a more rapid percolation, but the total salts removed in quantity is a little less than from Jars 14 and 16.

EXCHANGEABLE GASES AS AFFECTED BY TREATMENT AND LEACHING

An exchange of sodium for calcium on the ultra clay complex is found to take place with approach to neutrality caused by different treatments. Table 7 shows the replacement of sodium ion by the calcium ion on the ultra clay complex caused by the use of sulfur and leaching. It appears that between pH 9.0 and 8.3 the calcium becomes reactive and rapidly displaces the sodium. This soil at a pH above 8.5 tends to have a high concentration of sodium on the complex.

The ratio of sodium to calcium on the complex changes with the salt concentration of the soil solution. Some sodium will be removed from the complex when the concentration of salts in the soil solution is reduced. It is not necessary to neutralize the soil solution before exchangeable sodium will be replaced by calcium. A change in calcium concentration in the soil may cause a base exchange on the clay complex.

FIELD TRIALS WITH SULFUR AND OTHER FERTILIZERS ON CER-TAIN CROPS

Alfalfa field trials for these sulfur investigations have been centered at Redmond and Vale, Oregon.

Experiments with normal soil were conducted at Redmond, Oregon, the purpose being to determine the economic amount and form of sulfur to be applied per acre to Deschutes valley soils. Sulfur was applied at the rates of 50, 75, and 100 pounds per acre on two different farms; also, several different forms of sulfur were applied at the rate of 75 pounds per acre, on new seeding of alfalfa. Next year definite results should be secured from these two trials.

Sulfur applications, however, produced some increases in weight of crop, and these increases were visible during the growing season. Superphosphate, which contains sulfur, also increased growth.

Potato fertilizer trials indicate supplying nitrogen in some form to be necessary, as vine growth was increased noticeably during the growing season thereby. When the potatoes were harvested the tubers

fertilized with ammonium sulfate were larger than the ones unfertilized. Sulfates improve the color of potato foliage. Increased yields resulted from the complete fertilizers in all the trials.

ALKALI LAND RECLAMATION TRIALS

Alkali reclamation work at Vale has been in progress since 1921. Crops on the old plats of this field have been planted for several years, but the problem of reclaiming this land from an economic point of view has not been fully solved. It appears to have taken about 3000 pounds of sulfur an acre to reclaim this soil. It is at least doubtful if prevailing land values there will justify this expense.

A new series of plats were started in April, 1927, treated with newer forms and most promising combinations of sulfur to find some means of reclaiming this land with less expense than was involved on the older plats. Alkali "greasewood land" was cleared and fitted in one-tenth acre strip border plats. Treatments were applied at the rates and forms shown, table 9.

Fertilizers were harrowed in and the soil maintained as moist fallow until August, then copious irrigations were applied to leach out the excess salts until late September, when the whole range of plats was seeded to rye, with alfalfa and sweet clover. The stand secured is indicated in the table No. 9 as observed 4 weeks after seeding.

The initial hydrogen-ion concentration of alkali land as determined from composite soil samples was pH 10.4. As reclamation progresses, chemical determinations are being made periodically to note the progress of neutralization of excess salts.

Table 9. Forms of Sulfur Used in Reclamation of Alkali Land. Vale, Oregon.

Plats	Per Cent Stand
11 Iron sulfate 1672 lbs. 1 T. manure	25
12 Ammonium sulfate 300 lbs. 1 T. manure	e 2
13 Manure 1 T.	0
14 Gypsum 700 lbs. 1 T. manure	25
15 Sulfur 300 lbs. 1 T. manure	10
16 Check	10
17 Sulfur 300 lbs. 1 T. manure	25
18 Sulfur 300 lbs., gypsum 500 lbs., 1 Tomanure	. 40
19 300 lbs. sulfur	10
20 300 lbs. black gas sulfur	8
21 300 " Bac-sul	5
22 700 * Gaseo	0
23 Sand sulfur 300 lbs. 1 T. manure	1
24 Sublimed sulfur 300 lbs. 1 T. manure	1
25 Tailings 300 lbs. 1 T. manure	1
26 Check	0

Check No. 26 had manure piled and stored on one corner for several years.

CONCLUSIONS

- 1. The new forms of sulfur were studied and found to include rapid oxidizing materials that should supply sulfate-ion needed for the early period of plant growth.
- 2. Black gas sulfur compared with inoculated sulfur oxidizes at approximately the same rate except on alkali soil. During the first eight weeks the inoculated material yielded sulfates more rapidly than black gas sulfur, after which time the two were found to yield about the same quality of sulfates.
- 3. Plants grown in pots that had sulfur in applications of 50, 75, 100 lbs. per acre, in combination with manure, all showed increases over the untreated pots. Little differences appeared between the 50, 75, and 100 lb. applications. The 50 lb. application on Deschutes Sandy Loam gave just as good returns as 100 lb. application when used in greenhouse trials.
- 4. Sulfur produces a decided flocculating effect on alkali soils. Soils treated with 4000 lbs. of sulfur are flocculated rapidly, while non-treated soils remain deflocculated. Flocculation starts as

neutrality is approached.

- 5. For reclamation of alkali soil sulfur is superior to any other single chemical, due to its neutralizing and bringing calcium-ion into solution, resulting in displacing sodium on ultra clay complex with calcium.
- 6. The percolate from untreated alkali soil decreases as the time of leaching increases; deflocculation increases as leaching proceeds.
- 7. Laboratory studies combined with field trials indicate that the newer forms of sulfur tested have a promising future. Due to the colloidal form of the black gas product its use for control of disease and reclamation of alkali land offers some advantages over other available forms of sulfur of similar purity.
- 8. Under alkaline conditions sulfur appears to have increased the microflora of the soil, probably because of neutralizing alkali present, which produces a favorable flora for soil organisms.
- 9. Sulfur treatment of soils subjected to leaching causes calcium to become reactive and to displace the sodium on the ultra clay complex. For the soil employed a pH above 8.5 has a high concentration of sodium on the complex. Base exchange is a contin-

uous process and is affected by the concentration of salts in the soil solution.
