 Title:
 THE STRUCTURE AND THERMODYNAMIC PROPERTIES OF 2-BROMOETHANOL AS DETERMINED BY GAS PHASE ELECTRON DIFFRACTION

 Abstract approved:
 Redacted for privacy Kennèth Hedberg

The molecular structure of gaseous 2-bromoethanol has been investigated by electron diffraction with nozzle tip temperatures of 55 °C, 103 °C, 135 °C, 175 °C, and 200 °C. The molecule exists in both trans and gauche conformers at all of these temperatures. By least squares refinements the values for the mole fraction of the gauche conformer, x_{σ} , are as follows (in order of increasing temperature): 0.822 ± 0.097 , 0.863 ± 0.129 , 0.895 ± 0.139 , 0.859 ± 0.096 , and 0.812 ± 0.122 . The errors are 2 σ . Based upon a comparison of the areas of the peaks associated with the two conformers, the following values were obtained: 0.860, 0.848, 0.835, 0.785, 0.791. Calculation of $\Delta H_{t,g}^{O} = H_{t}^{O} - H_{g}^{O}$ and $\Delta S_{t,g}^{O} = S_{t}^{O} - S_{g}^{O}$ using the former set of data yields -0.107 ± 2.680 kcal./mole and -2.38 ± 6.77 e. u., respectively; using the latter set yields 1.15 ± 0.67 kcal./mole and 1.17 ± 1.69 e. u., respectively (using an estimated error in x_g of \pm 0.02 in the latter set of results). Both values are lower than corresponding values for 2-chloroethanol, the difference being attributed to a weaker intramolecular hydrogen bond and a greater

steric interaction in the 2-bromoethanol molecule than in 2-chloroethanol .

The structure of the molecule yielded results comparable to the other halo-ethanols. The following bond distances and angles were determined (associated amplitudes are in parentheses, errors are 2σ): C-C = 1.517 ± 0.003 (0.045 ± 0.006), C-O = 1.417 ± 0.003 (0.045 ± 0.006), O-H = 0.996 ± 0.008, C-H = 1.096 ± 0.008, C-Br = 1.954 ± 0.003 (0.052 ± 0.005), /CCBr = 110.5 ± 0.4, /CCO = 110.7 ± 0.7, dihedral /BrCCO = 66.1 ± 1.5. In the above values distances and amplitudes are in angstroms, angles in degrees. These values are "average" values resulting from least squares refinements using data from all temperature experiments simultaneously and correspond to an "average" temperature of 134 $^{\circ}$ C.

The Structure and Thermodynamic Properties of 2-bromoethanol as Determined by Gas Phase Electron Diffraction

ACKNOWLEDGEMENTS

I am especially grateful to Professor Kenneth Hedberg for accepting me as his graduate student and for his helpful supervision of this investigation.

I would like to thank cand. real Lise Hedberg and cand. real Kolbjorn Hagen for their help with computer programs as well as for their experienced suggestions.

In addition I wish to thank fellow graduate students Quang (Mike) Shen, Don Danielson, and Larry Eddy for their many helpful discussions and encouragement.

Finally, I would like to thank Chris for her patience.

THE STRUCTURE AND THERMODYNAMIC PROPERTIES OF 2-BROMOETHANOL AS DETERMINED BY GAS PHASE ELECTRON DIFFRACTION

ELECTRON DIFFRACTION METHOD

Only a very brief description of the experimental and theoretical aspects of electron diffraction will be given here. More detailed discussions of scattering theory are available from other sources (8) as well as more complete descriptions of the electron diffraction methods used regularly by our group. Some aspects of the method have been made more efficient and an up-dated description of them is planned for the future.

The apparatus accelerates a beam of electrons through a potential difference of 40-50 kV. The beam is collimated by a series of apertures and focused by a magnetic lens to a point on a photographic plate. The beam passes at right angles through a small jet of the vapor to be studied. The diffracted electrons are circularly symmetric about the undiffracted beam and form a pattern of diffuse rings on the photographic plate. The plates are developed and the density measured by scanning along a diametrical line using a modified (9) Joyce-Loebl microdensitometer while the plates are rotated about the center of the diffraction rings. The data are then reduced (7, 11) to complete the experimental procedure.

The equation relating the total scattered intensity to the components of that intensity may be written in the following form:

$$s^{4}I_{t} = k \sum_{i,j} \frac{|A_{i}||A_{j}|}{sr_{ij}} \exp(-\langle \delta \ell_{ij}^{2} \rangle s^{2}/2) \cos|\Delta \eta_{ij}| \sin(r_{ij}s)$$
$$+ k \sum_{i} A_{i}^{2} + k \sum_{i} Z_{i}S_{i} + I_{ext}$$

 $= I_{m} + I_{a} + I_{i} + I_{ext}$ (1)

where I_m , I_a , I_i , and I_{ext} stand for, respectively, the structure sensitive scattering, atomic scattering, incoherent scattering, and extraneous scattering. The quantities A_i are the electron scattering amplitudes multiplied by s^2 and Δn_{ij} the phase shifts between atoms of atomic numbers, Z_i and Z_j . The variables r_{ij} , ℓ_{ij} , and s are, respectively, the interatomic distances, the root-mean-square amplitude of vibration, and the diffraction variable ($s = 4\pi\lambda^{-1}sin\theta$). S_i is the incoherent scattering factor and λ is the wavelength of the electrons. I_a , I_i , and I_{ext} are not dependent upon the structure of the molecule and are subtracted as a smooth background from s^4I_t .

In an electron diffraction investigation of a molecule existing in two different conformations, e. g., gauche and trans, the total structure sensitive scattered intensity can be expressed as the sum of the scattering due to each conformer as follows:

$$I_{m} = x_{gauche} I_{m} + x_{trans} I_{m}$$
(2)

where x and x trans are the mole fractions of the gauche and the trans conformers, respectively.

The actual structure determination begins with the determination of a trial structure deduced from the fourier transform

of the intensity data. The fourier transform is related to the probability P(r) of finding an interatomic distance in the molecule between r and r + dr, and is often termed the radial distribution curve. The calculation of the radial distribution curve is done as follows:

$$\frac{P(r)}{r} = \frac{2}{\pi} \sum_{\substack{s \\ s \\ min}}^{s} I'(s) \exp(-Bs^2) \sin(rs)\Delta s$$
(3)

where the factor $\exp(-Bs^2)$ reduces the error associated with the finiteness of the intensity data, and $I'_m(s)$ is a "constant coefficient" curve obtained by multiplying I_m by sZ_kZ_1/A_kA_1 , which helps produce Gaussian-shaped peaks. $I'_m(s)$ is given by the equation

$$I'_{m}(s) = k \sum_{i=1}^{\infty} \frac{A_{i}A_{j}Z_{i}Z_{j}}{A_{k}A_{1}r_{ij}} \exp(-\langle \delta \ell_{ij}^{2} \rangle s^{2}/2) \cos|\Delta \eta_{ij}| \sin(r_{ij}s)$$
(4)

The actual refinements are done by adjusting the parameters in the expression given above in equation (1) for I_m so that the difference between the calculated and experimental intensity curves is minimized.

INTRODUCTION

It is generally recognized (14,21,22) that the 1,2-dihaloethanes (XCH_2-CH_2Y) , where X and Y are F, Cl, Br, or I atoms) exist as two rotational conformers, the trans and the gauche. The trans appears to be the more stable, perhaps because of electrostatic repulsions between the electronegative halogen atoms. When one of the halogen atoms is replaced by a hydroxyl group, the opportunity exists for an attractive interaction between the OH group and the X atom which does not exist between two halogen atoms; this attractive interaction owes to the formation of an intramolecular hydrogen bond. Should the strength of such a bond be sufficiently great, it will dominate the repulsive interactions and one may expect the gauche rotamer to be more stable than the trans.

Several groups of researchers (4, 5, 6, 15, 16, 17, 19, 22) have studied the infrared and/or the Raman spectra of the 2-haloethanols. In almost every case evidence has been found for the coexistance of both the trans and the gauche conformations (although the gauche form is often indistinguishable from a mixture of cis and trans forms). The only exception in solution or vapor phase is that 2-fluoroethanol may exist almost entirely in the gauche form, at least at convenient temperatures. Microwave studies (2, 13) have supported these conclusions. As far as electron diffraction is concerned, a recent investigation of gaseous 2-fluoroethanol in our laboratory (10) found no evidence of the

trans conformation even at a rather high temperature. Likewise, early electron diffraction studies of 2-chloroethanol (3, 20) failed to detect any trans conformer, but the experiments were done at low temperatures where only a small percentage of trans would be expected. A more recent electron diffraction experiment (1) utilizing new developments in the technique has detected a substantial amount of the trans conformer at higher temperatures, and at least some of the trans form at lower temperatures. No electron diffraction experiments have been reported for 2-bromoethanol.

The difference in energy between the trans and the gauche conformations of the 2-haloethanols is of considerable interest. By determining the ratio of gauche to trans forms at a particular temperature, one determines an equilibrium constant from which the free energy difference may be obtained. Moreover, by repeating this determination at different temperatures, the enthalpy and entropy differences between the two conformations may be calculated. The values obtained for the enthalpy differences between the conformations from different types of experiments have usually been in the range of about one to two kilocalories per mole for 2-chloroethanol and slightly less for 2-bromoethanol, with the trans form being the less stable.

Gas phase electron diffraction may be used in certain cases to measure the relative amounts of the trans and gauche conformers at various temperatures. In the case of 2-bromoethanol, figure 1 shows that while many of the interatomic distances are basically the same in the two conformations, the distance between the largest two

atoms, oxygen and bromine, is quite different. The large atomic numbers of these atoms causes them to be good scatterers of high energy electrons. A theoretical radial distribution curve (Figure 2) for a mixture of the two conformations shows prominent peaks at the interatomic distances corresponding to the Br··O interaction in each of the conformations. The area of each peak is proportional to $x_i^2 C_{Br}^2 r_{Br}^{-1} \cdots r_{i}$, where x_i is the mole fraction of that conformer. Thus, the electron diffraction analysis at a given temperature yields both the composition of the sample at that temperature and the overall structure of 2-bromoethanol.

THERMODYNAMIC EXPRESSIONS FOR CONFORMATIONAL ANALYSIS

The interconversion of the gauche conformer and the trans conformer can be expressed by the following equilibrium expression (1):

gauche
$$\neq$$
 trans (5)

for which the equilibrium constant is

$$K = \frac{x_t}{x_g}$$
(6)

where x_t and x_g are the mole fractions of the trans and the gauche conformers, respectively.

The expression for the Gibbs free energy,

$$\Delta G^{O} = -RT1nK , \qquad (7)$$

leads to

$$-R\ln \frac{x_{t}}{x_{g}} = \frac{\Delta H^{\circ}}{T} - \Delta S^{\circ} . \qquad (8)$$

The entropy difference (ΔS^{O}) in equation (8) is the entropy change for the reaction of equation (5), i. e., the standard entropy for trans molecules minus that for gauche molecules. Now, because there are two equivalent forms of gauche molecules and only one of trans, the standard entropy of the former includes a statistical factor of Rln2. If one is interested in the standard entropy difference between the trans and one of the gauche conformers $(\Delta S^{O}_{t,g})$, one has

$$\Delta S^{O} = S_{t}^{O} - S_{g}^{O} - R \ln 2 \qquad (9)$$
$$= \Delta S_{t,g}^{O} - R \ln 2 \cdot \qquad (10)$$

Equation (8) becomes

$$-R\ln \frac{x_t}{x_g} = \frac{\Delta H^{\circ}}{T} - \Delta S_{t,g}^{\circ} + R\ln 2 . \qquad (11)$$

Rearranging and combining terms gives

$$\operatorname{Rln} \frac{2x_{t}}{x_{g}} = \frac{\Delta H^{\circ}}{T} - \Delta S^{\circ}_{t,g} . \qquad (12)$$

Equation (12) is the equation of a straight line in the slopeintercept form. A straight line fitted to a plot of $-Rln\frac{2x}{x}t$ versus 1/T will yield a y-intercept equal to $-\Delta S_{t,g}^{O}$ and a slope equal to ΔH^{O} .

In the case of conformation analysis studied at extremely low pressures, the partial pressures of the two conformers can be assumed ideal. Since under these circumstances $\Delta(PV) = 0$, we have

$$\Delta H^{O} = \Delta E^{O}. \tag{13}$$

EXPERIMENTAL AND DATA REDUCTION

A sample of 2-bromoethanol was obtained from Eastman Kodak Company. The infrared spectrum compared favorably with that given by Wyn-Jones and Orville-Thomas (19). Nuclear magnetic resonance scans were taken on both 100 MHz. and 60 MHz. instruments and appeared to be of pure 2-bromoethanol. There was a possibility of some water being present because its infrared and nmr peaks could have been obscured by those for 2-bromoethanol. However, the areas of the nmr peaks suggested that there could be no more than five percent water in the sample. The sample boiling point was determined to be 149.6°C; the literature value is 150.3°C. The sample was used without further purification.

For a sample vapor pressure of 10-15 torr, which experience shows is necessary for diffraction photographs of a molecule of this type, a sample bath temperature of about $55^{\circ}C$ was required. This temperature is thus the minimum nozzle-tip temperature; lower nozzle temperatures would have led to condensation in the nozzle. Electron diffraction photographs were made at both the long and the middle camera positions using 8 x 10 inch Kodak lantern slide (medium) plates. Because the diffraction data were very weak at about s equal to 25 or 30, no short camera plates were exposed. Experiments were carried out at five different nozzle temperatures: $55^{\circ}C$, $103^{\circ}C$, $135^{\circ}C$, $175^{\circ}C$, and $200^{\circ}C$. At least five plates were exposed at each camera distance for each temperature. Exposure data are listed in Table 1.

All of the usable plates were scanned in the usual manner (18) using a modified (9) Joyce-Loebl microdensitometer. The potentiometer output was sent through a voltage to frequency converter and the digitalized results automatically punched on paper tape. The data was read into the computer and was reduced using a computer program written by Lise Hedberg. Smooth backgrounds were calculated for the curves using another program written by Lise Hedberg. As the structure refinement proceeded, this background program was used to obtain progressively better backgrounds and thus to improve the experimental intensity data. More complete descriptions of the data reduction are available elsewhere (7, 9, 11).

STRUCTURE DETERMINATION AND CONFORMATIONAL ANALYSIS

In order to obtain trial values for the principal geometrical and vibrational parameters, a radial distribution curve was calculated according to equation (3) using a composite intensity curve made by combining data from one middle camera plate and one long camera plate from the $55^{\circ}C$ experiment. The radial distribution curve (like figure 2) has important peaks at 1.02, 1.47, 1.95, 2.40, 2.86, 3.23, and 4.12 (angstroms), which are due, respectively, to following distances in the molecule: C-H and O-H, C-C and C-O, C-Br, C·O, C·Br, Br·O_g, and Br·O_t. From these peak positions sufficiently accurate parameter values were obtained to permit least squares refinements to be done.

A coordinate and distance subroutine was written to be used with the standard least squares computer program now used by the electron diffraction group. Some simplifying assumptions were made because of the relative complexity of the structure arising from the lack of symmetry in the molecule: 1) The structures of the trans and the gauche conformers were assumed to be identical except for the distances changing with rotation about the carbon-carbon bond. 2) The plane formed by the HCH atoms around each C were assumed to bisect the angle formed by the C and the other two atoms attached to it. 3) Both HCH angles were assumed equal. With these assumptions the geometry of the molecule may be described by the following parameters: <C-C,O> (the average of the C-C and the C-O bond lengths), Δ (C-C,O) (the difference between the C-C and the C-O

bond lengths), r(C-BR) (the C-Br bond length), $\langle C, O-H \rangle$, $\Delta(C, O-H)$, $\underline{/CCBr}$ (the CCBr bond angle), $\underline{/CCO}$, $\underline{/COH}$, $\underline{/HCH}$, $\underline{/CCOH}$ (the angle of rotation about the C-O bond with 0° being with the alcoholic H cis to the β -C), $\underline{/BrCCO}$ (the angle of rotation about the C-C bond, 0° being with the Br and the O eclipsed), and $r(Br \cdot \cdot O)_t$ (the trans $Br \cdot \cdot O$ nonbond length). The final parameter was put in as a separate refinable variable to allow for a possible shortening of the nonbond length in the case that the trans rotational angle, $\underline{/BrCCO}$, is not exactly 180° .

Besides the twelve geometrical parameters listed above, there were the compositional parameter, x_g (the mole fraction of the trans conformer in the sample), and 23 vibrational amplitude parameters associated with distinctly different distances in the molecule. Not all of these variables could be refined, it was discovered, so that some had to be given values taken from other diffraction experiments on less complicated molecules.

Several steps were taken to assure comparable results for the experiments run at different temperatures: 1) Only the best three long camera plates and the best three middle camera plates were selected from the experiments at each temperature. 2) The ranges of data from corresponding plates from each temperature were chosen to be identical. 3) The composite curves from the five temperatures were placed on a common amplitude scale using an average theoretical curve as basis of comparison.

Although the overall structure of the molecule was readily

determined, even with the precautions taken as mentioned above to obtain comparable results, the determination of the composition (the variable x_g) proved to be very difficult. Three parameters which are sensitive to the conformation, the amplitudes of the gauche and the trans Br··O distances and also the trans Br··O distance, were poorly determined by the least squares refinements judging from their respective standard errors. It was also found that simultaneous refinement of the r(Br··O)_t distance, its amplitude of vibration and the composition was impossible. Thus, one of these variables had to be held constant to obtain values for the others.

Different values for the amplitude were inserted and held constant while the other variables were allowed to refine. It was found that for a wide reange of values for the amplitude, only small differences in the other variables were obtained. Variation of the $r(Br \cdot 0)_t$ distance, however, made much larger differences in the values of the refined variables. Hence, an approximate value for the amplitude was inserted and held constant during refinements of the other variables.

The amplitudes of all the distances were expected to increase systematically with temperature, and the results demonstrated such a trend. To compensate for this temperature dependence, the ratio of the refinable amplitudes at one temperature to those at another temperature was calculated and used to adjust those amplitudes which were held constant during the actual refinements.

Even with these corrections, the standard errors associated with the composition parameter, $x_{\sigma}^{}$, were large with respect to the values themselves (Table 2). Plotting the radial distribution curves for the five different temperature experiments (Figure 4), a noticeable trend was observed in the relative sizes of the outermost major peak, namely that associated with the $r(Br \cdot \cdot 0)_{tr}$ distance. This trend seemed to be lacking in the values obtained from the least squares refinements for x_g , although the error limits associated with these values could easily include such a trend. To get some empirical data for this apparent trend, the peaks associated with the gauche and the trans Br••O distances were cut out and weighed. The weights of these peaks, just as the areas, are proportional to the mole fractions of the two conformers divided by their respective Br.O distances. This predicts a linear dependence on the ratio of the peak weights to the composition parameter, x_{g} . Therefore, three theoretical intensity curves were calculated, which were identically the average of the five final models obtained from least squares with the exception of the compositional parameter. The radial distribution curves were calculated and plotted (Figure 5). The appropriate peaks were cut out and weighed. A plot of x_g versus the ratio of peak weights (trans to gauche), yielded a straight line, as predicted. The ratios obtained from the experimental curves were converted to x_g values on the basis of the plot. For the five experiments in order of increasing temperature, the \mathbf{x}_{g} values obtained in this manner are as follows: 0.860, 0.848, 0.835, 0.785, and 0.791. The values obtained for x_g from the least squares refinements,

arranged in the same order are as follows (errors are 2σ): 0.822 ± 0.097, 0.863 ± 0.129, 0.895 ± 0.139, 0.859 ± 0.096, and 0.812 ± 0.122. Comparing these two sets of results, one may detect a noticeable trend in the first set which seems to be lacking in the second.

The geometrical and vibrational parameters proved to be well determined by the least squares refinements. Moreover, the values varied only slightly from one experimental temperature to another (with the exception of the systematic trend of the amplitudes as described above). Because of the slight variance of the geometrical parameters, all the data was used together in one large refinement, yielding a set of "average" values for the refined parameters corresponding to an "average" temperature of 134 $^{\circ}$ C (Table 3).

DISCUSSION

Nothing unusual was found in the final structure of 2-bromoethanol. The r(C-C) and the r(C-O) values are in good agreement with values reported on 2-chloroethanol and 2-fluoroethanol (Table 5). There is an apparent trend of increasing /CCX in the series X = F, Cl, Br. There may also be a trend of increasing torsional angle, /XCCO, in the gauche form for the same series. Both of these trends can be understood in terms of increasing steric interactions between the oxygen and the halogen atoms as the halogen atom increases in size. Another noticeable and expected trend is the increase in amplitude values as the temperature is increased.

Although the conformational analysis proved to be more difficult than was originally anticipated, it is felt that some conclusions may be drawn. The values for the conformational parameter obtained from the least squares refinements had extremely large errors associated with them (Table 2). A plot of $-\text{Rln}\frac{2x}{x_g}$ versus 1/T yielded a least squares straight line of nearly zero slope (Figure 6). The thermodynamic quantities ΔH^0 and $\Delta S^0_{t,g}$ were determined to be -0.107 ± 2.680 kcal./mole and -2.38 ± 6.77 e. u., respectively. Using the values for the conformational parameter obtained by weight comparisons of the radial distribution peaks associated with each particular conformer, other values for ΔH^0 and $\Delta S^0_{t,g}$ were obtained: 1.15 ± 0.67 kcal./mole and 1.17 ± 1.69 e. u., respectively. The data used to determine the latter values fit a straight line much better than the least squares data (Figure 7).

The errors given for the latter values correspond to an estimated error of ± 0.002 in the x_g values.

Values obtained for ΔH^{0} (or ΔE^{0}) for 2-chloroethanol (16, 17, 22) have been in the range 0.95 - 2.60 kcal./mole and for $\Delta S_{t,g}^{0}$ in the range 3.6 - 7.4 e. u. The present study suggests that ΔH^{0} has a lower value in the case of 2-bromoethanol than in the case of 2-chloroethanol. This corresponds to a gauche form which is not quite as stable relative to the trans form as in the 2-chloroethanol molecule. This can readily be understood as arising from a lower Br. H bond strength relative to the Cl. H and also to a larger steric repulsion between the Br and O atoms than between the Cl and O atoms.

There is also an apparent difference in the entropy values obtained for the two molecules: 2-bromoethanol has a lower value for $\Delta S_{t,g}^{O}$ than does 2-chloroethanol. This corresponds to a trans form which is more nearly equal in entropy to the gauche form than in the 2-chloroethanol molecule.

Table 1. Data for electron diffraction photographs used for the structure determination of 2-bromoethanol. All plates were 8X10 inches. The usable s-range for the 75 cm. nozzle to plate distance was from 2.00 to 10.75 and for the 30 cm. distance was from 8.00 to 28.00.

Table 2. Final structural results for 2-bromoethanol for the five different temperature experiments.^a

Table 2. Continued.

^aDistances (r_a) and root-mean-amplitudes (l) are in Angstroms, angles are in degrees. Parenthesized values were assumed. Bracketted values were set equal and refined as a group.

^bThe ratio (R) is given by the expression: $R = \left[\sum_{i=1}^{\infty} w_{i} \Delta_{i}^{2} / \sum_{i=1}^{\infty} w_{i} I_{i} (obs)^{2}\right]^{1/2}$, where $\Delta_{i} = I_{i} (obs) - I_{i} (calc)$ and w_{i} are weighting factors.

Table 5. Comparison of 2-bromoethanol with 2-chloroethanol and 2-fluoroethanol.^a

^aDistances (r) are in Angstroms, angles are in degrees. Reported errors from microwave and electron diffraction do not necessarily have the same meaning.

Table 6. Experimental intensity data $[sI_m(s)]$ for 2-bromoethanol. Long camera distance (75 cm) plates have an s-range from 2.00 to 10.75, middle camera distance (30 cm) plates have an s-range from 8.00 to 28.00.

Figure 1. Gauche (left) and trans (right) conformations and atom
 numbering of 2-bromoethanol.
 Br: 1, 1'
 C: 4, 5
 H: 2, 2', 3, 3', 6, 7, 9
 O: 8

Figure 2. Average final theoretical radial distribution curve for 2-bromoethanol showing the relative contributions for the different interatomic distances with the atoms numbered as in Figure 1.

Figure 3.

Composite experimental intensity curves for 2-bromoethanol for the five different temperature experiments. The lower five curves are the difference curves (i. e., experimental minus theoretical) using theoretical curves determined independently for each experiment.

Figure 4. Radial distribution curves for 2-bromoethanol calculated from the experimental curves given in Figure 3.

Figure 5. Theoretical radial distribution curves identically equal to the average final theoretical curve in Figure 2 except for the percentage of the trans conformer as given on the figure.

Figure 6. Thermodynamic plot using the least squares values for x at each temperature. The best straight line has a slope of -0.107 and a y-intercept of 2.38.

Figure 7. Thermodynamic plot using values for x_g obtained from a weight comparison of peaks.
