AN ABSTRACT OF THE THESIS OF

Eileen Lukens for the degree of Honors Baccalaureate of Science in Environmental Engineering and Honors Baccalaureate of Science in Sustainability presented on June 3, 2019. Title: Anaerobic Dehalogenation of Trichloroethene by Encapsulated *Dehalococcoides mccartyi*

Abstract approved: _____

Lewis Semprini

Chlorinated aliphatic hydrocarbons (CAHs) like trichloroethene (TCE) were mostly used to replace drying cleaning fluids which contained hydrocarbons like benzene, and were highly flammable. Through improper disposal, storage, and spills, TCE and its downstream products, like cis-dichloroethene (cDCE) and vinyl chloride (VC), leached into groundwater and threaten human and environmental health. An anaerobic organo-halide respiring bacterium, *Dehalococcoides mccartyi*, can be used to completely dehalogenate TCE to ethene, a non-toxic end-product. *Dehalococcoides mccartyi* uses CAHs as electron acceptors and hydrogen as the electron donor. *Dehalococcoides mccartyi* is a strict anaerobe. Because of this, field tests with anaerobic bacteria must include technologies to protect cultures from oxygen exposure during injection into contaminated wells. Currently, nitrogen blankets are used to protect cultures, but these technologies can be expensive. These challenges could be addressed through anaerobic encapsulation, the process of entrapping cells in a gel matrix to act as a physical barrier between bacteria and the surrounding environment. In addition, encapsulation is an inexpensive technology.

The objective of this study was to determine the methodology for anaerobically encapsulating a culture highly enriched with *Dehalococcoides mccartyi* in sodium alginate gel matrix, compare suspended cell performance with encapsulated cell performance, and determine the effects of oxygen on encapsulated cells. These objectives were achieved by creating an anaerobic 4% wt sodium alginate gel bead solution and combining it with the culture in an anaerobic glove box resulting in a 2% wt sodium alginate – culture solution. Beads were formed by extrusion through a 23G needle into a 0.25% calcium chloride solution. Encapsulated *Dehalococcoides mccartyi* produced TCE dehalogenation rates comparable to suspended culture. However, gel beads deteriorated after two weeks. In addition, rates of TCE dehalogenation decreased after exposure to 0.97% oxygen in the headspace.

Key Words: Bioremediation, Chlorinated Solvents, Encapsulation, Anaerobic, *Dehalococcoides*

Honors Baccalaureate of Science in Environmental Engineering and Honors Baccalaureate of Science in Sustainability project of Eileen Lukens presented on June 3, 2019.

APPROVED:

Lewis Semprini, Mentor, representing School of Chemical, Biological, and Environmental Engineering

Tyler Radniecki, Committee Member, representing School of Chemical, Biological, and Environmental Engineering

Mohammad Azizian, Committee Member, representing School of Chemical, Biological, and Environmental Engineering

Toni Doolen, Dean, Oregon State University Honors College

I understand that my project will become part of the permanent collection of Oregon State University, Honors College. My signature below authorizes release of my project to any reader upon request.

Eileen Lukens, Author

Acknowledgements

I would like to thank so many people for supporting me on my journey to completion of this project. First, I would like to acknowledge my undergraduate professors who gave me all the tools I needed to be a successful engineer. I would not be who I am today without them.

I would like to thank Dr. Lewis Semprini for taking me under his wing and supporting me for the past four years. He truly enriched my college experience and not only mentored me in the lab but also helped further my professional and academic career. He always made me feel welcomed and supported. I could not have asked for a better mentor than him. Not to mention he throws great dinner parties.

I would also like to thank Dr. Mohammad Azizian for his mentorship and for being on my committee. Mohammad saved me more times than I can count and knew how to soothe any machine in the lab. He took the time to walk me through procedures and showed me everything I needed to succeed in the lab as well as became a great friend.

I would also like to thank Dr. Tyler Radniecki for his mentorship and for being on my committee. Dr. Radniecki challenged me to push my analysis of a problem to the next level and supported me in my classes along the way.

There are so many graduate student mentors I want to thank who answered my silly questions, were patient with me, and taught me skills in the lab and in life. I especially want to thank Hannah Rolston for being my mentor from day one in the lab and not only teaching me everything I know about how to work in a lab, but also for supporting me in my fellowships and graduate school applications. She is truly an inspiring woman and we need more people like her in the world. I would also like to thank Mitchell Rasmussen, Riley Murnane, and Jon Laurance for countless laughs and Alyssa Saito, Emma Ehret, Marina Cameron, and Krysta Krippaehne for

being empowering women that I aspire to be. I would also like to thank all the other graduate students who came to my aid despite being in different labs like Ashley Berninghaus and Rich Hilliard who lent their knowledge and kindness.

I want to thank my mom, without her I wouldn't be a scientist. She inspires me every day to do my best and to move through the world with confidence. She also supported me every step of the way with late night phone calls and soothing words to alleviate my anxieties.

I would like to thank my undergraduate coworkers who supported me and created a lovely environment to work in like Willow Walker, Allison Burns, and Stephanie Wright. I would especially like to thank my favorite partners in crime, Grant Kresge and Gillian Williams for making me laugh every day. I would also like to extend my gratitude to the countless undergrads in the lab space like Gabi Garza, Elmira Fathe Azam, and others. I would especially like to thank my best friend since sixth grade and lab adjacent partner, Nora Honeycutt, for countless therapy sessions and being my editor while writing our theses. And of course, I would like to thank all my peers outside of the lab who supported me: Manasi Vyas, Sydney Clark, Lauren Roof, Julia Whitaker, and my wonderful partner Cori Elam.

Finally, I want to thank everyone who funded me in my undergraduate career like the those involved in the Sophomore Women Engineering Fellowship, the Johnson Internship Program, the Clean Water Initiative Summer Undergraduate Research Fellowship.

Thank you all!

Literature Review

History

Chlorinated aliphatic hydrocarbons (CAHs) were mostly used to replace drying cleaning fluids which contained hydrocarbons like benzene, which were highly flammable¹. Carbon tetrachloride (CT) was one of the first chlorinated solvents to be used in the dry-cleaning industry due to its low flammability¹. However, it also had applications in floor wax, paints, and essential oil extraction¹. Usage of CT began to decline when it was discovered that in the presence of moisture and heat, phosgene gas could be produced¹. Many people were concerned over this because phosgene gas was used as a deadly choking weapon in WWI².

In the 1930s, trichloroethene (TCE) and tetrachloroethene (PCE) began to phase out CT due to better recovery methods for those chemicals, but also reduced metal corrosion¹. PCE was used in dry cleaning and many similar industries as CT¹. TCE was widely used as it was the most effective cleaning and degreasing agent¹. Similar to PCE, TCE's high recovery rate, non-flammability, and non-corrosivity made it an ideal candidate for usage in industry¹. TCE was also used in textiles, general anesthetics, many household cleaning agents, and even in the decaffeination of coffee¹. Its use continued until 1960 when the environmental movement found its footing in the United States¹.

Chlorinated solvents leached into ground water through leaky storage tanks, accidental spills, and improper waste disposal³. Chlorinated solvents can partition between gas and liquid phases following Henry's law⁴. When pure liquid phase of a chlorinated solvent leaks into the subsurface, a dense non-aqueous phase liquid (DNAPL) can form⁵. The formation of DNAPLs are particularly problematic as they act as long-lasting sources of contamination. When water in an aquifer passes through a zone containing a DNAPL, chlorinated solvents dissolve into the passing fluid and can be transported throughout the aquifer. In addition to being distributed as DNAPLs, chlorinated

solvents can also sorb to soils⁵. Sorption is a significant problem in the ground as it traps chlorinated solvents in the solids and aquifer material and makes them difficult to clean⁵. All these various attributes of chlorinated solvents are a concern because they pose risks to human and environmental health. A 1975 study by the National Cancer Institute found that exposure to TCE can cause cancerous tumors to form in mice⁶. In addition, aquifer-fed wetlands are at risk for contamination. A study conducted on four species of North American amphibians found that both PCE and TCE disrupt the development of amphibian embryos⁷.

Increased pressure to have strict regulations of industrial chemicals led to the reduced usage of chlorinated solvents. In addition, the 1970 Clean Air Act caused regulation of TCE and PCE emissions due to concerns of ground-level and ozone smog¹. Trichloroethane (TCA) was introduced to replace TCE, but was eventually banned for similar reasons¹. Furthermore, the dumping of toxic wastes was banned in 1976 under the Resource Conservation and Recovery Act⁸. Eventually, in 1980 the Comprehensive Environmental Response, Compensation, and Liability Act (CERLA) was passed by Congress in response to public concern from toxic waste incidents such as Love Canal, New York⁸. CERLA was the first nationwide emergency response program of its kind providing toxic waste information and enforcing hazardous waste clean up⁸. Within CERLA, a trust fund (often referred to as Superfund) was created in order to support the clean-up of toxic waste. Following that in 1983, the EPA created the National Priority List (NPL) which specified 406 sites of concern to be cleaned up under the Superfund¹. TCA, PCE, TCE, and CT were the four most common contaminants found at the Superfund sites¹.

Treatment Options

Several methods of treatment for groundwater contamination exist including chemical, thermal, physical, and biological treatment. Chemical treatment options include oxidation and reduction¹. In-situ chemical oxidation has the advantage of rapid treatment⁸. In addition, the proper

oxidant can treat a variety of chemicals⁹. Furthermore, the end products of in-situ chemical oxidation are generally innocuous⁹. However, chemical oxidation can also mobilize metals in the groundwater⁹. The oxidant can be consumed by other materials in the aquifer as well as the target materials⁹. Furthermore, in-situ chemical oxidation is not ideal for groundwater with dilute and low concentrations of contaminants⁹. Thermal treatment options include electric resistive heating, thermal conductive heating, and hot fluid injection¹. Thermal treatment can quickly and reliably clean up chlorinated solvents; however, the act of heating the soils damages their natural properties¹⁰. In addition, there has been little work to improve this technology despite its success¹⁰. Physical treatment includes air stripping, activated carbon, bioventing, and soil vapor extraction¹. In soil vapor extraction, clean air is pumped into contaminated soil areas and then the contaminated air is pulled out with vacuums¹¹. Pump and treat is another common method of cleanup. In this system, contaminated water is pumped to the surface and then treated with air stripping or another technology¹². Air stripping is effective for highly volatile compounds but must be used in conjunction with another technology in order to transform the contaminant into a non-toxic product¹³. Biological treatment methods, often referred to as bioremediation, utilize microorganisms to clean groundwater¹. Bioremediation is advantageous in that some native microbes to the aquifer can be stimulated to degrade chlorinated compounds without the need for bioaugmentation¹⁴. However, bioremediation is a much slower process than other treatment options and has limited success in high concentrations of contaminants as these conditions can be toxic to microorganisms¹³. Bioremediation will be the focus of this review.

Bioaugmentation

Bioaugmentation is one form of bioremediation and is the process of introducing non-native microbes into the subsurface in order facilitate desired microbial reactions. Bioaugmentation is

advantageous for several reasons. For one, bioaugmentation reduces the time frame for remediation compared to biostimulation¹. Biostimulation is the process which remediates contaminated sites by enhancing aquifer conditions for native microbial populations^{15,16}. In addition, bioaugmentation can be useful when native dechlorinating species are present at low concentrations or when biostimulation is unsuccessful if the microorganisms are well adapted to degrading compounds of interest¹. Bioaugmentation has been successful in field-scale tests as well as at wastewater treatment plants^{17,18}.

Microorganisms can respire chlorinated solvents both aerobically and anaerobically. The metabolism of microorganisms allows certain species to degrade chlorinated solvents. Aerobic cometabolism is the process by which a microbe, in the presence of certain substrates, will produce unique enzymes that degrade chlorinated solvents. In the case of aerobic cometabolism, VC and cDCE can serve as electron donors^{19,20}. Another type of respiration is the anaerobic reductive dehalogenation pathway with hydrogen as the electron donor²¹. In this case, chlorinated solvents act as the electron acceptors. Anaerobic respirators have an advantage over aerobes in that they can transform chlorinated solvents at higher concentrations making them effective for DNAPL clean up¹. This second type of respiration will be the focus of this review.

Anaerobic reductive dehalogenation can be performed by a variety of organo-halide respiring bacteria (OHRB)²². There are various species of OHRB including *Desulfitobacterium*, *Geobacter*, and *Dehalococcoides mccartyi*²². *Dehalococcoides* have various reductive dehalogenation proteins (rdhA) responsible for the de-chlorination of solvents²². PceA dechlorinates PCE to TCE. TceA dechlorinates TCE to ethene and VcrA dechlorinates TCE, DCE, and VC to ethene²² (Figure 1). However, *Dehalococcoides mccartyi* more efficiently dechlorinates TCE when other electron

acceptors like DCE and VC are present, making competition with other OHRB key to the success of *Dehalococcoides*²³.

Figure 1: Reductive dehalogenation of TCE. Hydrogen acts as the electron donor and replaces the chlorines. The chlorinated solvents act as electron acceptors and chlorines become an acid in solution.

Anaerobic bacteria lack certain enzymes that protect them from damaging oxygen reduction products²⁴. Reduction products such as the superoxide anion and free hydroxyl radical are damaging to the cells²⁴. Aerobic and facultative microbes compensate for these harmful products with the production of an enzyme called superoxide dismutase²⁴. Anaerobic cells like *Dehalococcoides mccartyi* do not have this protective enzyme and are therefore harmed in the presence of oxygen. This inhibits the ability of *Dehalococcoides mccartyi* to perform reductive dehalogenation, particularly the dechlorination of vinyl chloride to ethene²⁵.

Common practice for keeping *Dehalococcoides mccartyi* protected from oxygen exposure during field implementation includes transporting the culture in a steel carrying vessel under a nitrogen blanket (Figure 2)^{26,18}. A pilot test to transform PCE to ethene at the Kelly Air Force Base near San Antonio, Texas was conducted with a bacterial consortium containing phylogenetic relatives to *Dehalococcoides ethenogenes*²⁶. The culture was transported to the site under a N₂/CO₂ atmosphere in 8-L stainless steel vessels²⁶. Furthermore, to reduce the amount of oxygen at the site, the water column and air in the well was sparged with argon before the culture was introduced to the well with an argon-flushed delivery line²⁶.

Encapsulation

Cell immobilization has been investigated for medical applications²⁷. However, environmental applications are just emerging. One form of cell immobilization is gel encapsulation which has minimal loss of cell viability²⁸. These gel matrices can be made of natural or synthetic polymers and are usually formed into small 1-5 mm diameter beads²⁸. Generally, polymers are selected based on the desired gel properties such as mechanical strength, porosity, and hydrophobicity²⁸. However, cell growth inside the polymers can degrade the mechanical strength of the matrix and cause the matrix to deteriorate²⁸. Encapsulation can be performed with a variety of polymers such as alginate, cellulose, gellan gum, and others²⁸. Interestingly, alginate is derived from brown algae and can gel by cross-linking with calcium²⁷ (Figure 3). However, ionically cross-linking can be unstable due to the mobility of divalent cations which can attach to other compounds in media solutions²⁷.

Immobilization is of interest for *Dehalococcoides mccartyi* because it may protect the culture from oxygen and lead to better dispersion throughout aquifers in field applications.

Clogging of aquifers can occur in in-situ bioremediation due to the excessive growth of bacteria near the injection site²⁹. Encapsulated cells may reduce this effect. In a column packed with sand, gellan gum microbeads were found to distribute evenly throughout the column³⁰. In addition, encapsulation may provide a physical barrier between the cells and the environment potentially allowing time for the cells to acclimate to new conditions³¹. Immobilization can essentially create micro-environments for the cells inside the more hostile macro-environment of an aquifer³². Gel matrices could potentially control diffusion rates of contaminants to the cell which is of interest to *Dehalococcoides mccartyi* with regards to oxygen.

Objectives

This project aimed to address several key objectives including...

- Determining the methodology for anaerobically encapsulating a culture highly enriched with *Dehalococcoides mccartyi* in sodium alginate gel matrix
- Comparing suspended cell performance to encapsulated cell performance
- Determining if encapsulation will protect cells from oxygen exposure

Materials and Methods

Dehalococcoides mccartyi was encapsulated by creating an anaerobic 4% wt sodium alginate solution and combining with an equivalent volume of culture to create a 2% wt sodium alginate-culture solution. Encapsulated cells were then exposed to TCE to compare rates of degradation with non-encapsulated cells in solution (suspended cells). A flow chart of the encapsulation procedure can be found in Figure 4. Table describing materials and solutions used can be found in Table 3, Appendix B.

Victoria-Stanford 2L Culture

The dehalogenating culture used in this study was the Victoria-Stanford consortium. The Victoria-Stanford 2L (VS2L) culture originated from a PCE-contaminated site in Victoria, Texas³³. Native *Dehalococcoides* were identified as one of the dechlorinating species at this site³⁴. In the Semprini laboratory, *Dehalococcoides* and other OHRB in the VS2L culture have been developed into a robust population in a continuous stir tank reactor (CSTR). Due to the slow growth of this culture, the mean hydraulic residence time of the CSTR is 50 days²³ (Figure 5). The CSTR receives a continuous feed of saturated TCE to its solubility limit in water. Prior to this encapsulation experiment, the VS2L culture was fed formate excess (45mM), deficit (25mM), and finally formate excess again²³. Excess formate allows for the production of hydrogen to complete dechlorination and also acts as a buffering mechanism to prevent changes in pH during dechlorination³⁵. Furthermore, the culture was effective at stably transforming TCE to ethene²³.

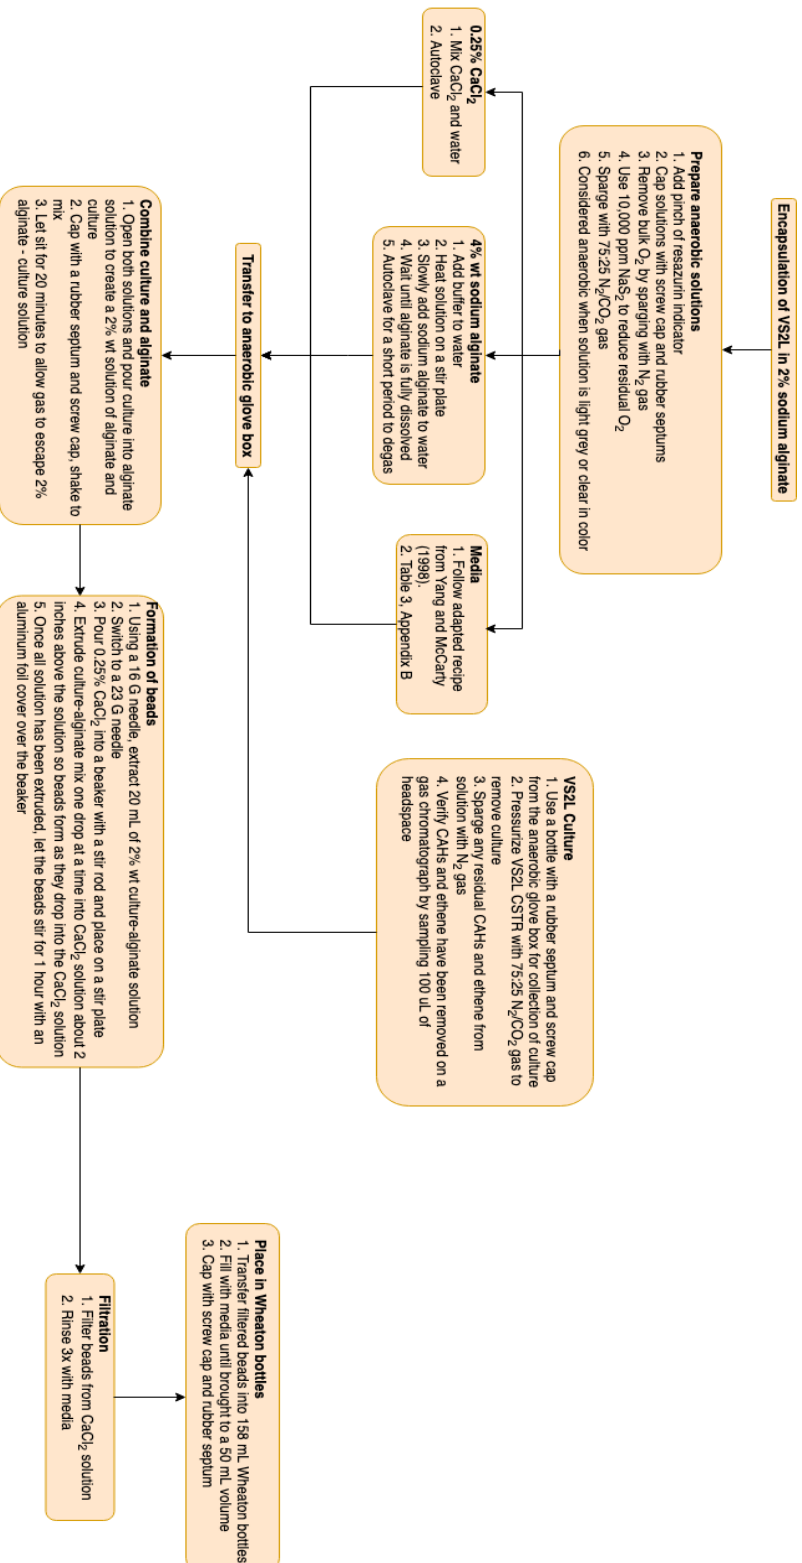

Figure 4: Flow chart of encapsulation procedure

Figure 5: VS2L CSTR (left) containing mixed *Dehalococcoides*. Reactor fed by saturated TCE and 45mM formate (right). Retention time of 50 days.

Creating Anaerobic 4% Alginate Solution

The alginate solution was based on studies conducted by Mitchell Rasmussen and Paige Molzahn^{36,37}. In a laminar flow hood, 60 mL of deionized water and 1 mL of solution 2 were added to a 250 mL borosilicate Wheaton bottle with a screw cap. The solution was heated and stirred on a stir plate. In small increments, 2.4 g of sodium alginate was added to the mixture to create a 4% sodium alginate solution. The mixture was very viscous and dissolved slowly. The pH was checked with a paper pH strip to ensure a pH of 7. The sodium alginate was then autoclaved for 5-10 minutes to sterilize the mixture. The alginate was left to cool to room temperature. The 4% sodium alginate was transferred to an autoclaved 250 mL borosilicate glass Wheaton bottle with a screw cap, rubber septum, and stir bar. Before capping, a small pinch of resazurin was added to the bottle

to act as an oxygen indicator. The bottle was then placed in an up-flow hood with a stir plate. As the solution was mixed, the 4% alginate was sparged with nitrogen gas to remove oxygen. After 20 minutes, 0.3 mL of 15,000 ppm sodium sulfide was added as a reductant to the bottle through the rubber septum and bubbled for another 20 minutes with purified 75:25 N₂/CO₂ gas. Process was considered complete when gel transitioned from dark blue to pink to a semi-clear grey which indicated oxygen was not present and anaerobic conditions were achieved (Figure 6).

Figure 6: 4% wt sodium alginate gel transitioning from blue to pink to grey. Bottle capped with screw cap and rubber septum.

Culture Collection

158 mL borosilicate bottles were retrieved from the anaerobic glove box. The gas headspace of the VS2L culture was checked using a gas chromatograph to ensure that complete transformation of TCE to ethene was occurring inside the CSTR. A tube furnace was heated to 600°C where 75:25 N₂/CO₂ gas was purified and used to pressurize the VS2L culture. Liquid sample lines were cleared of oxygen by running culture through the lines and collecting the liquid in a waste container. Liquid samples were then collected into 158 mL Wheaton bottles with rubber

septums and screw caps. As sample was collected, a gas needle was placed into the rubber septum to release pressure. Once the desired culture volume had been obtained (180 mL), CSTR was returned to normal function and sample lines were closed. Culture that had been collected was then purged with N₂ gas for 20 minutes to remove residual gases and CAHs. Removal of CAHs was verified on a gas chromatograph.

Creating Anaerobic CaCl₂ Solution

Two solutions of approximately 400 mL of 0.25% CaCl₂ were autoclaved in 500 mL Wheaton bottles with a rubber septums and stir bars. After the solutions cooled, a pinch of resazurin was added as an oxygen indicator. The solutions were bubbled and stirred for 15 minutes with N₂ gas. The solutions were then bubbled with 75:25 N₂/CO₂ gas and 0.1 mL of 15,000 ppm sodium sulfide was added until the solution turned clear in color.

Suspended Cells

Suspended cell bottles were created by combining 10 mL of culture with 40 mL of anaerobic media in a 158 mL Wheaton bottle inside the anaerobic glove box. Suspended cell bottles were brought into the glove box to expose the cells to the same conditions the encapsulated cells would experience. The bottles were then capped with rubber septums and sealed with parafilm. Cell masses in each bottle were determined from a total suspended solids analysis of the VS2L CSTR to get cell concentrations. Then the total mass of cells inside each bottle was determined from the volume of cells added to each bottle multiplied by the VS2L CSTR cell concentration. The total cell mass inside each bottle was 0.46 mg.

Encapsulating Anaerobic Cells

The 4% wt alginate solution was combined with an equivalent volume of culture to create a 2% wt alginate and cell solution inside the anaerobic glove box. The result was an equivalent cell mass as in the suspended bottles of 0.46 mg. The bottle was capped with a screw cap and

rubber septum. The culture was shaken to mix and set aside to allow gas bubbles to exit the solution. Gel beads were created by doing the following procedure. Using a 16G needle, 20 mL of alginate and cell solution was collected into a 20 mL plastic syringe. The needle on the syringe was then switched to a 23G needle. On a stir plate, 130 mL of 0.25% anaerobic CaCl_2 solution was stirred in a beaker as alginate cell solution was slowly added one drop at a time into the CaCl_2 solution for cross-linking (Figure 7). The forming alginate-cell beads were allowed to cross-link for 15 minutes or 1 hour. The longer time was to create more strongly cross-linked beads. Beads were gravity filtered and washed three times with anaerobic media to ensure the removal of CaCl_2 solution. Each bead was estimated to have had 3.25×10^{-4} mg cells (Equation 5). Beads were then placed into 158 mL Wheaton bottles. Bottles were brought to 50 mL volume with anaerobic media and capped with a screw top and rubber septum. Once bottles were removed from the anaerobic glove box, caps were sealed with parafilm.

Figure 7: (A) 20 mL 2% sodium alginate with culture extruded through a 23G needle into a 0.25% CaCl_2 bath where the beads cured for 1 hour. (B) Beads gravity filtered from CaCl_2 solution and washed three times with anaerobic media. (C) Beads placed in 158 mL glass Wheaton Bottles and brought to 50 mL with anaerobic media. Sealed with parafilm. (D) 5 mL air added to the headspace of half the bottles. Pink color from resazurin indicator in media and beads.

Oxygen Exposure

All bottles contained a headspace of 108 mL. For both encapsulated bottles and suspended bottles, a 5 mL vacuum was pulled under an up-flow hood using a 5 mL plastic syringe. 5 mL of air was added to half the bottles so three bottles had a headspace with 0.97% oxygen (Equation 4). Bottles were shaken until solution turned pink from the reaction of oxygen with resazurin (Figure 7).

Experimental Start and Maintenance

All bottles were given 0.3 mL of TCE from the CSTR feed which contained saturated TCE to its solubility limit in water and excess formate (45 mM). This resulted in an initial liquid concentration of 32.4 μM TCE. Bottles were shaken vigorously and immediately measured on the gas chromatograph flame ionization detector to obtain initial measurements. This was considered the experimental start time. Degradation of TCE was monitored approximately every 20 minutes. In between sampling periods, bottles were stored in a 25°C dark room on a 200 rpm shaker table.

Analytical Methods

Gas Chromatography

TCE, cDCE, VC and ethene were measured on a Hewlet-Packard 6890 gas chromatograph with a flame ionization detector. The gas chromatograph contained an Agilent 115-3432 GSQ capillary column (30m x 530 μm x 0.00 μm normalized) with a max temperature of 250°C and 15 mL/min gas flowrate. TCE, cDCE, VC and ethene had retention times of 5.4, 2.7, 0.8, and 0.6 minutes respectively. By comparing peak areas produced by the analysis to standard curves, concentrations of contaminants in the gas phase were determined (Figures 76, 77, 78, 79, Appendix A). Then, using Henry's law and the volume of the gas and liquid compartments, the total mass of

contaminant was determined (Table 1 Appendix B; Equations 1, 2 Appendix C). For encapsulated cells, contaminants were assumed to not sorb onto the sodium alginate gel matrix.

Rate Modeling

Rates were determined using a linearization method as well as through an adapted sum of least squared errors modeling method. For the converted linear method, rates of transformation were determined by adding together all the masses of downstream chlorinated compounds of the compound of interest at each time point (Equation 3). Then a linear regression was fit to the data. For example, TCE transformation was determined from the addition of the masses of ethene, VC, and cDCE formed. Linearized rates were considered a good fit to the data if the R-squared values were greater than 0.98.

The non-linear sum of least squared errors method (referred to as “km” in the charts) uses weighted least-squares analysis to find the best-fit values from the integrated Monod equation³⁸. In general, this method produces more reliable results than linearized methods³⁸. For this study, the non-linear sum of least squared errors method was adapted to include the inhibition between chlorinated ethenes³⁹. The model includes the inhibitory effects of TCE on cDCE and VC dechlorination as well as the effects of cDCE on VC dechlorination to ethene³⁹. Because of this, the non-linear sum of least square errors model generally predicts higher degradation rates than the converted linear rates.

Results and Discussion

Four sets of experiments were performed (Figure 8). In each set for each cell condition, suspended or encapsulated, triplicate bottles were made. Three sets compared suspended cell performance versus encapsulated cell performance. Performance was judged based on the rates of degradation of chlorinated ethenes. Sets 1 and 2 saw multiple additions of TCE. Set 4 demonstrated the effects of oxygen on suspended and encapsulated cells.

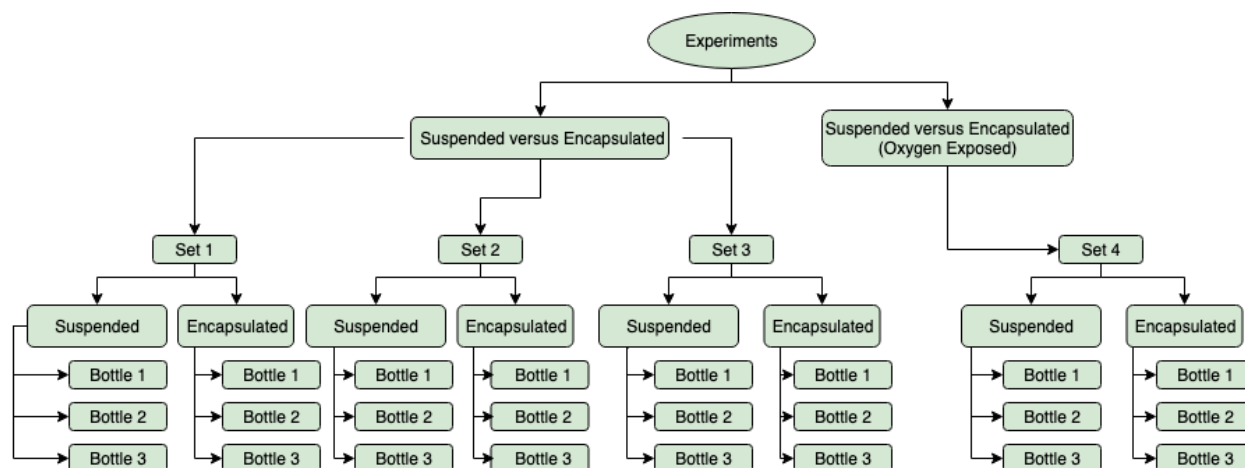

Figure 8: Experimental matrix

Set 1 – Suspended VS Encapsulated

The first set of suspended versus encapsulated cells showed successful encapsulation of *Dehalococcoides mccartyi*. Beads were spherical and 2-3 mm in diameter. Beads were non-uniform due to being formed by hand and not mechanically (Figure 9).

Figure 9: Size of biotic beads shown against a VWR ruler for scale. Beads were 2-3 mm in diameter. Pink color is a result from resazurin indicator reacting with oxygen in the surrounding environment.

Set 1 bottles were spiked with a liquid concentration of 32.4 μM TCE at the start of the experiment. Converted linear rates were found from the accumulation of downstream products

(Figures 10, 11). Converted linear rates did not account for the effects of inhibition between chlorinated compounds. Modeled rates (km) did account for effects of inhibition between chlorinated ethenes and therefore resulted in higher rates of chlorinated ethene degradation (Figures 12, 13). Higher rates of degradation were seen for sets 1-3 for modeled (km) rates. For set 1, modeled (km) degradation rates for TCE and VC fell within 1 standard deviation of each other for suspended cells and encapsulated cells (Figures 14, 15). DCE degradation rates fell within 2 standard deviations. This indicates that the mixed *Dehalococcoides* culture is resilient when encapsulated. Rates of degradation are proportional to those produced by Ehret (2018)⁴⁰.

Beads appeared to deteriorate after two weeks in solution on the shaker table at 200 rpm. This was indicated by the cloudiness of the media solution (Figure 16). Suspended cell bottles of the same age were not cloudy in appearance suggesting the presence of alginate was the cause of the cloudiness and not cell growth. Beads may have deteriorated for several reasons. Calcium is the cross-linking cation and may have been pulled from the gel matrix into solution due to the constituents that make up the anaerobic media (Table 2, Appendix B). Media constituents include sodium, phosphate, and magnesium. Literature suggests that constituents like these can contribute to gel deterioration²⁸. In addition, it is unknown whether *Dehalococcoides mccartyi* or other bacteria in the mixed culture may be able to use alginate as a substrate.

Figure 16: Photo of suspended and encapsulated cells for set 1 on the 3rd day of the experiment (left). Photo of the encapsulated cells 9 days after start of experiment (right). Media that encapsulated cells were suspended in appeared cloudy suggesting the alginate beads were deteriorating.

In an abiotic encapsulated bottle suspended in media and TCE, beads seemed to hold together better than those encapsulated with microbes but still experienced some degradation (Figure 17). Degradation of TCE occurred in this bottle but much slower due to the media properties for abiotic degradation of CAHs. Bead condition also degraded but much slower than biotic beads. In an abiotic encapsulated bottle suspended in deionized water (DI) and TCE, beads also seemed to hold together longer than biotic beads (Figure 18). Although only one trial was done, abiotic beads suspended in DI appeared to hold up only slightly better than abiotic beads suspended in media. Regardless, the presence of microorganisms seemed to have played a key role in the longevity of the beads. Interestingly, very little cell growth occurred per injection of TCE suggesting that perhaps a different microbially mediated process contributed to the degradation of the beads such as consumption of alginate as a substrate (Equation 6).

Figure 17: Deteriorated condition of abiotic beads suspended in media solution made August 21st, 2018. Photo taken April 1st, 2019.

Figure 18: Condition of abiotic beads suspended in DI solution made September 6th, 2018. Photo taken April 1st, 2019. Some degradation of beads over the 7-month period.

Set 2 – Suspended VS Encapsulated

Figure 19: Set 2 suspended (left) and encapsulated (right) cells on day 1 of experiment.

Set 2 resulted in encapsulated beads similar to those seen in Set 1 (Figure 19). Set 2 beads were also 2-3 mm in diameter and spherical in shape (Figure 20). For set 2, encapsulated cells were cured for 1 hour instead of 15 minutes in order to address stability issues with the bead. No difference in the longevity of the beads was seen between set 1 and set 2.

Figure 20: Size of biotic beads shown against a VWR ruler for scale. Beads were 2-3 mm in diameter. Pink color is a result from resazurin indicator reacting with oxygen in the surrounding environment.

Despite collecting the cells on the same day, the second set (set 2) of suspended and encapsulated cells performed very differently (Figures 21, 22, 23, 24, 25, 26). Suspended cells were not taken into the anaerobic glove box with the encapsulated cells. About halfway through the experiment, the suspended cells turned pink indicating exposure to oxygen hence the lower rates seen. Set 2 encapsulated cells performed well with slightly lower rates of degradation than set 1 likely due to cell collection for sets 1 and 2 occurring on different days (Figure 26).

Figure 21: Converted linear rates of degradation of chlorinated ethenes for suspended cells in set 2. Data points represent experimental data from bottle 1. Black lines represent linear trends. Set 2 suspended cells were done in triplicate. Figures 52 and 56 show the other two bottles for suspended cells.

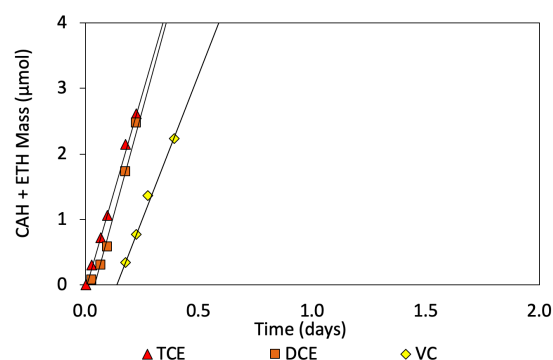

Figure 22: Converted linear rates of degradation of chlorinated ethenes for encapsulated cells in set 2. Data points represent experimental data from bottle 1. Black lines represent linear trends. Set 2 encapsulated cells were done in triplicate. Figures 53 and 57 show the other two bottles for encapsulated cells.

Figure 23: Model (km) rates of degradation of chlorinated ethenes for suspended cells in set 2. Data points represent experimental data from bottle 1. Solid lines represent model prediction. Set 2 suspended cells were done in triplicate. Figures 54 and 58 show the other two bottles for modeled suspended cells.

Figure 26: Rates of chlorinated ethene degradation for set 2 encapsulated cells. Bars represent an average of three trials. Error bars represent standard deviation between three trials. km represents non-linear sum of least squared errors model which accounts for inhibition while converted linear rates do not.

Set 3 – Suspended VS Encapsulated

The third set (set 3) of suspended cells and encapsulated cells performed similarly to each other (Figures 27, 28, 29, 30, 31, 32). Although cells for suspended and encapsulated reactors were collected on different days from the VS2L CSTR, cells were treated the same and suspended cells were exposed to the glove box environment. Rates of chlorinated ethene degradation in set 3 were slightly lower than those seen in set 1 which is likely due to the cells being collected on different days from the VS2L CSTR. Although dechlorination time for encapsulated cells appear longer than suspended cells, the rates are actually very similar as seen by the converted linear and non-linear modeled rates (Figures 31, 32). This is because 5x the cell mass was accidentally added to

the suspended cells. When looking at the converted linear and model rates based on cell mass, the rates are actually very similar. Modeled rates for suspended and encapsulated cells for TCE and DCE degradation were within 1 standard deviation of each other. Modeled VC rates of degradation for suspended and encapsulated cells fell within three standard deviations of each other.

Figure 27: Converted linear rates of degradation of chlorinated ethenes for suspended cells in set 3. Data points represent experimental data from bottle 1. Black lines represent linear trends. Set 3 suspended cells were done in triplicate. Figures 60 and 64 show the other two bottles for suspended cells.

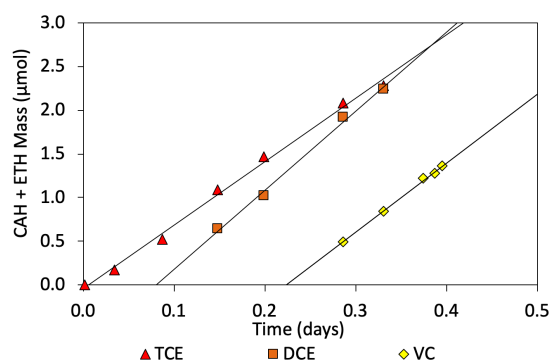

Figure 28: Converted linear rates of degradation of chlorinated ethenes for encapsulated cells in set 3. Data points represent experimental data from bottle 1. Black lines represent linear trends. Set 3 encapsulated cells were done in triplicate. Figures 61 and 65 show the other two bottles for encapsulated cells.

Figure 29: Model (km) rates of degradation of chlorinated ethenes for suspended cells in set 3. Data points represent experimental data from bottle 1. Solid lines represent model prediction. Set 3 suspended cells were done in triplicate. Figures 62 and 66 show the other two bottles for modeled suspended cells.

Figure 30: Model (km) rates of degradation of chlorinated ethenes for encapsulated cells in set 3. Data points represent experimental data from bottle 1. Solid lines represent model prediction. Set 3 encapsulated cells were done in triplicate. Figures 63 and 67 show the other two bottles for modeled encapsulated cells.

Figure 31: Rates of chlorinated ethene degradation for set 3 suspended cells. Bars represent an average of three bottles. Error bars represent standard deviation between the three bottles. km represents non-linear sum of least squared errors model which accounts for inhibition while converted linear rates do not.

Figure 32: Rates of chlorinated ethene degradation for set 2 encapsulated cells. Bars represent an average of three trials. Error bars represent standard deviation between three trials. km represents non-linear sum of least squared errors model which accounts for inhibition while converted linear rates do not.

Encapsulated cells were cured for 1 hour in set 3 just like set 2. Varying levels of gel matrix degradation were still seen (Figure 33). Bead diameters for the 3rd set of encapsulated cells ranged from 1-3 mm in diameter. Some beads became oblong or irregular in shape. All bottles in which the beads in Figure 33 came from were cloudy suggesting some alginate had dissolved into the bulk solution which aligns with what was seen in the bottles for sets 1 and 2.

Figure 33: Three different biotic bottles with varying levels of bead degradation shown against a ruler for scale. Some beads were still 2-3 mm in diameter (left) while others were ~1.5-2 mm in diameter (middle), and others became oblong in shape with diameters ranging from 1-3 mm (right). Pink color is from resazurin indicator. Photos were taken 4 months after beads were created.

Set 4 – Suspended VS Encapsulated (Oxygen Exposed)

Rates of dechlorination for oxygen exposed beads and suspended cells were lower than non-exposed cells (Figures 34, 35, 36, 37, 38, 39). The sodium alginate matrix did not protect the cells from damage at an oxygen concentration of 0.97%. Oxygen exposed beads appeared to perform better than suspended cells when exposed to oxygen; however, there was insufficient data

to determine if the dechlorination rates between suspended and encapsulated cells were statistically significant (Figures 38, 39). In addition, modeled (km) rates of degradation were lower than converted linear rates likely due to the fact that oxygen inhibition is not included in the model.

Figure 34: Converted linear rates of degradation of chlorinated ethenes for suspended cells exposed to 0.97% oxygen in the headspace in set 4. Data points represent experimental data from bottle 1. Black lines represent linear trends. Set 4 suspended cells were done in triplicate. Figures 68 and 72 show the other two bottles for suspended cells.

Figure 35: Converted linear rates of degradation of chlorinated ethenes for encapsulated cells exposed to 0.97% oxygen in the headspace in set 4. Data points represent experimental data from bottle 1. Black lines represent linear trends. Set 4 encapsulated cells were done in triplicate. Figures 69 and 73 show the other two bottles for encapsulated cells.

Error bars represent standard deviation between bottles. km represents non-linear sum of least squared errors model which accounts for inhibition while converted linear rates do not.

Figure 39: Set 4 encapsulated cells exposed to 0.97% oxygen in the headspace. Bars represent an average of three bottles. Error bars represent standard deviation between bottles. km represents non-linear sum of least squared errors model which accounts for inhibition while converted linear rates do not.

Set 1 and 2 – Multiple additions of TCE

Set 1 received five additions of TCE (Figures 40, 41). Suspended cells in set 1 were done in triplicate for the multiple additions. Encapsulated cells for set 1 were done in duplicate for multiple additions of TCE. However, encapsulated bottles appeared cloudy after two weeks suggesting cells had entered suspension from the breakdown of the alginate matrix by the time the third spike of TCE was given. Despite this, suspended and encapsulated cells appeared to perform similarly suggesting that even after encapsulation, *Dehalococcoides mccartyi* have the potential to maintain TCE degradation rates.

Figure 40: Set 1 suspended cells in triplicate that received multiple additions of TCE. Data points represent experimental data. Dashed lines are a visual aid to follow trends. Error bars present the standard deviation between three bottles.

Figure 41: Set 1 encapsulated cells in duplicate that received multiple additions of TCE. Data points represent experimental data. Dashed lines are a visual aid to follow trends.

Set 2 received two additions of TCE (Figures 43). Suspended and encapsulated cells in set 2 were done in triplicate for the multiple additions of TCE. However, as discussed previously, suspended cells for set 2 were exposed to oxygen and had reduced performance as a result. Due to this fact, set 2 encapsulated cells were compared to the suspended cells for set 1. Similar to results of set 1, set 2 encapsulated cells had a similar performance to set 1 suspended cells (Figures 42, 43). This again suggests *Dehalococcoides mccartyi* is resilient after encapsulation.

Figure 42: Set 1 suspended cells that received multiple additions of TCE on a shorted time axis. Data points represent experimental data. Dash lines are a visual aid for viewing trends. Error bars represent the standard deviation between three bottles.

Figure 43: Set 2 encapsulated cells in triplicate that received two additions of TCE. Data points represent experimental data. Dashed linear are a visual aid to follow trends. Error bars represent the standard deviation between three bottles.

Conclusions

The *Dehalococcoides mccartyi* mixed culture can be encapsulated in a 2% wt sodium alginate gel matrix without large reductions in dechlorination rates. However, due to gel stability, encapsulation with sodium alginate is not viable in the long term. Preliminary evidence from control bottles suggest that the growth of cells may play a part in destroying the gel matrix. The gel matrix did not protect the anaerobic cells from a headspace of 0.97% oxygen as seen by the drop in dechlorination rates once exposed. There was insufficient data to tell if encapsulated cells exposed to oxygen performed significantly better than suspended cells exposed to oxygen. This study led to the following conclusions...

- A method was successfully developed to encapsulate *Dehalococcoides mccartyi* in an alginate gel matrix by fabrication in an anaerobic glove box
- Encapsulation was reproducible as indicated by similar rates of chlorinated ethene degradation from three batches of cells.
- Diffusion of chlorinated ethenes in and out of gel matrix did not inhibit the reductive dehalogenation process.
- Encapsulated *Dehalococcoides mccartyi* was not protected from 0.97% oxygen in the headspace and experienced a decline in chlorinated ethene degradation rates.
- Encapsulated cells began to break apart after 2 weeks and the alginate began to dissolve back into the bulk solution.
- Encapsulated cells are able to transform multiple additions of TCE with similar performance to suspended cells.

Future Work

Future experiments will aim to address the stability of the sodium alginate gel matrix. This could be done by changing the makeup of the media to remove anti-chelating agents or adding additional chemicals to increase stability. Literature suggests that polyethyleneimine, glutaraldehyde, polyvinyl alcohol or partial drying may be used to increase stability of the gel matrix²⁸. Furthermore, attempts of covalently cross-link alginate rather than ionically cross-link the alginate may be more successful for long term stability of the gel matrix²⁷. Studies using gellan gum have also found long term viability for aerobically encapsulated bacteria³⁶. Once bead stability has been established, future work investigating the rebound potentially for encapsulated cells versus suspended cells once exposed to oxygen can be investigated. Potential projects that could stem from this work include the testing of anaerobic beads in flow conditions as well as full scale well testing.

Table 3: List of materials for encapsulation

Material	Quantity	Preparation
Scoopula	2	(1)
Stir Bars	2	(1)
500 mL Glass Beakers	2	(1)
Plastic Filter Funnel	1	(1)
158 mL Borosilicate Wheaton bottles	6	(1)
20 mL plastic syringe	2	(2)
23 G Needle	2	(2)
16G Needle	2	(2)
500 mL Nitrogen Purged Waste Bottle	1	(1)
pH strips	--	--
0.25% $CaCl_2$	800 mL	(3)

Material	Quantity	Preparation
Anaerobic Media*	800 mL	(3)
15,000 ppm NaS ₂	1mL	--
Solution 2**	1 mL	--
Chemicals		
Name	Brand	Purity (%)
Resazurin	Aldrich Chemical Company	98
Alginate	Spectrum Chemical MFG Corp.	99
Trichlorethylene	Alt Aesar	99.9
1,2-dichloroethylene	Alfa Aesar	99
Vinyl Chloride	Aldrich Chemical Company	99.5
Ethene	Airgas	--

* Media solution adapted from Yang and McCarty (1998)³³ (See Table 2).

**See Table 4

- (1) Materials autoclaved and wrapped in tinfoil with vent holes and placed in anaerobic glove box 48-72 hours in advance of experiment.
- (2) Sterile plastic syringes were opened in the anaerobic glove box and filled with chamber gas 3 times before being left filled for 48-72 hours in advanced of experiment due to oxygen trapped in plastic pores. Needles packages were opened for the same reason.
- (3) Solution made anaerobic before entering glove box.

Table 4: Solution 2 constituents

Chemical	Mass (g)
K_2HPO_4	155
NaH_2PO_4	85
Ultra-pure water	1000 (mL)

Appendix C: Equations

Nomenclature

Symbol	Variable	Units
M_t	Mass total	mg
V_g	Volume of gas compartment	L
V_l	Volume of liquid compartment	L
C_g	Concentration in the gas phase	mg/L
C_l	Concentration in the liquid phase	mg/L
H_{cc}	Dimensionless Henry's Constant (C _g /C _l)	--
H_{pi}	Henry's Constant	M/atm
R	Ideal gas constant	L·atm/mol·K
n_{TCE}	Moles TCE	mol
n_{cDCE}	Moles cDCE	mol
n_{VC}	Moles VC	mol
n_{Ethene}	Moles Ethene	mol

Symbol	Variable	Units
P	Pressure	atm
V	Volume	L
T	Temperature	K
C_1	Oxygen concentration of atmospheric air	%
C_2	Oxygen concentration in headspace of reactor	%
V_1	Volume of air added	mL
V_2	Headspace of reactor	mL

Equations

(1) *Total Mass of a CAH*

$$M_t = V_g C_g + V_l C_l$$

(2) *Henry's Law*

$$H_{cc} = C_g / C_l$$

(3) *Converted Linear Rate Mole Totals*

$$n_{TCE} = n_{cDCE} + n_{VC} + n_{Ethene}$$

$$n_{cDCE} = n_{VC} + n_{Ethene}$$

$$n_{vc} = n_{Ethene}$$

(4) *Creating a 0.97% Oxygen headspace*

$$C_1 V_1 = C_2 V_2$$

$$C_2 = \frac{C_1 V_1}{V_2}$$

$$C_2 = \frac{(0.21)(5 \text{ mL})}{(108 \text{ mL})} = 0.0097 \rightarrow 0.97\%$$

(5) *Estimating cell mass per bead*

$$\frac{0.46 \text{ mg cells}}{20 \text{ mL gel}} = 0.023 \frac{\text{mg cells}}{\text{mL gel}}$$

$$\text{Volume of Bead} = \frac{4}{3} \pi r^2$$

Assume uniform bead diameter, $D_{bead} \cong 3 \text{ mm}$

$$\text{Volume of Bead} = \frac{4}{3} \pi (1.5 \text{ mm})^2 = 14.14 \text{ mm}^3 = 0.01414 \text{ cm}^3 = 0.014 \text{ mL}$$

$$\text{Mass cells per bead} = \frac{0.01414 \text{ mL}}{\text{bead}} \left(0.023 \text{ mg} \frac{\text{cells}}{\text{mL}} \right) = 3.25 \times 10^{-4} \frac{\text{mg cell}}{\text{bead}}$$

(6) *Estimating cell growth after one addition TCE*

$$\text{Protien produced per dechlorination} = \frac{0.006 \text{ mg Protien}}{\text{umol Cl}^{-}\text{-dechlorinated}} \text{ (Estimation from a similar dechlorinating culture } ^{42}$$

$$\text{Moles chlorine dechlorinated } 2.5 \text{ umol TCE} * 3 \text{ Cl}^{-} = 7.5 \text{ umol Cl}^{-}$$

$$\frac{0.006 \text{ mg Protien}}{\text{umol Cl}^{-}\text{-dechlorinated}} (7.5 \text{ umol Cl}^{-}) \left(\frac{2 \text{ mg TSS}}{\text{mg protien}} \right) = 0.09 \text{ mg TSS generated per spike TCE}$$
