Title: Meadowfoam Oil Yield as Influenced by Dry Matter Production and Partitioning, Flower Nupper, and Honep pee Density Redacted for Privacy
Abstract Approved: $\qquad$ Y Dr. Gałf Dr-Jolliff

Meadowfoam (Limnanthes alba Hartw. ex Benth. ssp. alba cv. Mermaid) seed yield, and consequently oil yield, varies considerably among years. Stable and high oil yield is needed to encourage profitable commercialization. Reports in the literature indicate that a negative relationship exists between seed yield (and thus oil yield) and total above-ground dry matter (phytomass) and that pollination may be limiting seed yield. The objective of this research was to create differing phytomass production, phytomass partitioning, flower phenology, and number of open flowers to determine the association of oil yield and its components with the cumulation and partitioning of phytomass, and pollination.

Transparent floating crop cover and shade cloth were used on field plots to alter light and temperature. Cover Early, Cover Early Plus Late and Shade treatments were applied 22 Jan. 1988 and 24 Jan. 1989. Shade and Cover Early were removed at the beginning of rapid elongation of stems 29 Mar. 1988 and 28 Mar. 1989; and Cover Early Plus Late was removed two weeks later, 12 and 11 April, respectively. Oil yield was consistently increased by the Shade and the Cover Early treatments. Increases in oil yield were related primarily to increases in flower number and seed number. Eighty-seven percent of the treatment variation in seed number was explained by cumulated
foraging bee density, cumulated open flowers and the synchronous occurrence of both. No relationship was apparent between phytomass two weeks after the beginning of rapid elongation of stems and seed yield. However, phytomass two weeks after the beginning of rapid elongation of stems did have a negative relationship with the weight seed ${ }^{-1}$, but the magnitude of the effect was small. The number of open flowers was found to be correlated with the percent of phytomass in stem tissue at the beginning of flowering. Fewer but heavier primary stems during rapid reproductive development were traits associated with higher yields. Leaf area development was accelerated by covering or shading, and partitioning to leaf tissue declined during rapid stem development.

Improvement in meadowfoam seed yield may be accomplished through increases in flower number via switching phytomass partitioning from vegetative to reproductive tissue during rapid stem development and through better pollination.

# Meadowfoam Oil Yield as Influenced by Dry Matter Production and Partitioning, Flower Number, and Honey Bee Density

This thesis is a testimony to Jehovah, Jesus Christ, and the Holy Spirit who has sustained me through this degree. Many times I wondered if or when I would finish this Ph.D., especially with the family problems that occurred. However, God's strength is perfected in our weaknesses and the Lord Blessed me by allowing me to attain this goal as well as being there consistently for the family.

Many people encouraged me and selflessly helped me to attain this goal. Suzie, my heart goes out to you and always will, for the help you gave me the first two years, and the challenge in life you are now working through. Thanks to Dustin and Ashley, how I appreciate your love and the time we shared together during these years. Two more loving or better behaved children no father can claim. May the Spirit of God dwell in your hearts forever.

A special thanks to Gary Jolliff, for selecting me and giving me the opportunity and freedom to learn about science and the scientific method. Thanks also for understanding my family needs which made this thesis possible (God works through people, God Bless You) and being a source of encouragement.

Thanks to Majid Seddigh for sharing his time and wisdom especially in the art of Journal Article preparation. A special thanks to Tim Fiez for friendship, wisdom, unmeasurable support, and partner in conducting growth analysis. Tim, I know that you will be a success at whatever you do, but we both know we won't do growth analysis again. I would like to thank Bob Franz, Tom Jahns, and especially Jim Crane for the sharing of their understanding of meadowfoam.

Thanks to my extended family for their support. A special thanks to mom who has been immeasurable support for my education in general.

Thanks to Dr. R. Kleiman and B.S. Phillips of the USDA-ARS Northern Regional Research Center for seed oil content determinations. This research was financially supported by Agriculture Experiment Station and the USDA-ARS Specific Cooperative Agreement 58-5114-8-1021.

The data included in the thesis were collected in 1987-1988 and 1988-1989. Tim Fiez assisted me in the planning, hiring of labor, and conducting of the experiments. The work was accomplished in cooperative manner, since our experiments were intermingled. The amount of work involved between both degree programs was tremendous.

Dr. Gary D. Jolliff's contribution to these experiments included 1) generating research funding, 2) providing equipment and facilities, 3) recruiting me to identify limiting factors to yield, 4) advising during the research, 5) critical review and guidance in the writing of scientific results.

Dr. Majid Seddigh was also very helpful by 1) assisting in generating research funding, 2) assisting in the recruitment of me, 3) advising me during the experiment, 4) critical review and guidance in the writing of results.

Because of many years of working with meadowfoam, Jim Crane was able to help me identify problems with prior experiments and, if possible, ways to avoid them. Jim's personal experience in the field gave me a better understanding of the influence of the environment on meadowfoam, which was helpful since little has been published in this area.

Chapter I has been submitted to Agronomy Journal. Chapter II is currently in Departmental Review and will be submitted to Crop Science for publication. Chapter III will soon be submitted for Departmental Review and then be submitted to Crop Science.

Meadowfoam Oil Yield as Influenced by Dry Matter Production and Partitioning, Flower Number, and Honey Bee Density

## INTRODUCTION

This thesis is written in manuscript format. It reports the following three studies: 1) "Shading and Crop Cover Effects On Meadowfoam Oil Yield", 2) "Flower Production and Honey Bee Density Effects On Meadowfoam Seed Yield", 3) "Meadowfoam Phytomass Development Effects On Flower Production".

Meadowfoam (Limnanthes alba Hartw. ex Benth.) is a native to the west coast of North America, more specifically to California, southern Oregon, and Vancouver Island, British Columbia. Its native environment changes from flooded in the winter to arid in the summer. In some locations the lack of winter precipitation may inhibit germination. Meadowfoam has evolved many mechanisms which enable it to compete and survive under these conditions. Our interest focuses on increasing oil yield and decreasing production costs, thereby stimulating the commercialization of a profitable alternative crop. Our objective is to domesticate meadowfoam into an agronomic crop for the purpose of optimizing profitable oil yield. However, this places meadowfoam in an environment considerably different and from that of wild meadowfoam, and the life cycle strategy of native genotypes most likely will not maximize oil production.

Previous work has provided indirect evidence that phytomass production has a negative relationship with oil yield (Pearson and Jolliff, 1986b; Krebs and Jain, 1985) and led to speculation that pollination was limiting oil yield (Calhoun and Crane, 1978; Gentry and Miller, 1965). More recent work has shown that seeds flower ${ }^{-1}$ is related to measures of honey bee density (Pearson and Jolliff, 1986a; Jahns and Jolliff, 1990). Chapter I explores the negative relation-
ship between oil yield and phytomass production. Chapter II looks at seed set as influenced by pollination and flowering. Finally, Chapter III looks at flower production as influenced by phytomass production and phytomass partitioning.

## CHAPTER I

SHADING AND CROP COVER EFFECTS ON MEADOWFOAM OIL YIELD

## ABSTRACT

Meadowfoam (Limnanthes alba Hartw. ex Benth. ssp. alba cv. Mermaid) seed yield, and consequently oil yield, has varied considerably among years. Stable and high oil yields are needed to encourage profitable commercialization. This experiment tested the hypothesis that phytomass (total above-ground dry matter) at the beginning of rapid elongation of stems (early April) is negatively associated with seed yield. Shade cloth and a transparent floating crop cover were used to alter light and temperature, compared to the Control. Cover Early, Cover Early Plus Late and Shade treatments were applied on 22 Jan. 1988 and 24 Jan. 1989. Shade and Cover Early were removed at 29 Mar. 1988 and 28 Mar. 1989; and Cover Early Plus Late was removed after an additional two weeks. Shade increased oil yield an average of $47 \%$ through higher (35\%) seed yield and higher ( $8 \%$ ) percent oil content. Seed yield and oil content were positively correlated with seed number area ${ }^{-1}$. The shaded plants had 24\% less phytomass, 28\% fewer stems, and $27 \%$ more open flowers than the Control. Cover Early increased seed and oil yield in both years while Cover Early Plus Late was inconsistent. In 1987-1988, Cover Early Plus Late increased oil yield $97 \%$ with fewer (14\%) but heavier ( $63 \%$ ) stems, $83 \%$ more seed number $a^{2 r e a}{ }^{-1}$, and $21 \%$ higher percent oil content than the control. Seed yield improvement by all treatments was associated with fewer primary stems, more flowers that opened, and greater seed number area ${ }^{-1}$. These results suggest that environmental and management practices which result in a reduced number of primary stems per plant would both increase and stabilize oil yield.

## INTRODUCTION

#### Abstract

Meadowfoam is a herbaceous winter annual domesticated at Oregon State University (Jolliff, 1981) for its unique seed oil (Earle, et al., 1959; Nikolava-Damyanova, et al., 1990). Seed yield, and consequently oil yield, has varied significantly among years. Higher and more stable oil yields are needed to increase economic attractiveness.

There is little information available on meadowfoam growth as related to oil yield. Also, no growth stage definitions have been developed for the crop. Averaged over treatments, Pearson and Jolliff (1986b) reported a large variation between years in total aboveground dry matter (phytomass) in mid-April. Oil yield in the lowphytomass year was $181 \%$ greater than when phytomass was high, suggesting a negative relationship between phytomass in mid-April and oil yield. In California, Krebs and Jain (1985) found oil yield of L. alba accessions to be negatively correlated with both crop growth rate and leaf area at 88 days after sowing. Weather data from the Oregon State University Hyslop Research Farm for 1984-1987 showed large variations in precipitation and diurnal fluctuation in temperature from year to year during winter months which may create considerable differences in phytomass production. All these factors led to the hypothesis that phytomass at the beginning of rapid elongation of stems (early April) is negatively associated with seed yield. The beginning of rapid elongation of meadowfoam stems generally occurs in late March in the Willamette Valley of Oregon.

Floating crop covers have been used to alter air temperature (Hall, 1971; Shadbolt and McCoy, 1960; Wells and Loy, 1985). In strawberry (Fragaria $x$ ananassa Duch.), time of flowering, fruit set, and fruit ripening were hastened in direct relation to the length of
time row covers were left in place in the spring (Gent, 1990). Growth rates of cucumber [Cucumis sativus (L.)] were increased by use of covers (Wolfe et al., 1989). Shade cloth reduces the amount of light received by a crop, suppresses dry matter production, and may influence partitioning of assimilates within crop canopies (Early et al., 1967; Egli, 1988; Hang et al., 1984).

The objective of this experiment was to create differing phytomass development before the beginning of rapid elongation of stems, and to determine: (i) phytomass production at two weeks after the beginning of rapid elongation of stems, (ii) oil yield and yield components, and (iii) the association of $i$ with $i i$.

Field experiments were conducted at Oregon State University Schmidt Research Farm ( $44^{\circ}$ and $38^{\prime} \mathrm{N}, 123^{\circ}$ and $12^{\prime} \mathrm{W}$ ) near Corvallis, OR in 1987-1988 and 1988-1989 on an Amity silt loam (fine-silty, mixed, mesic Argiaquic Xeric Agialboll). A fallow year preceded planting each season. Prior to planting, the concentrations of $N, P$, and $K$ in the top 30 cm of soil were determined. Nitrogen, $P$, and $K$ levels were 7,36 , and $160 \mathrm{mg} \mathrm{kg}^{-1}$ in 1987-1988 and 6,44 , and 218 mg kg in 1988-1989, respectively. Soil pH was 5.6 in 1987-88 and 5.8 in 19881989. Fifty-four kg ha of N and 29 kg ha of P were incorporated pre-planting both seasons. Fifty-six $\mathrm{kg} \mathrm{ha}^{-1} \mathrm{~N}$ was broadcasted on 23 Feb. 1988 and on 28 Feb. 1989. The meadowfoam cultivar 'Mermaid' was planted in $15-\mathrm{cm}$ rows on 1 Oct. 1987 and 6 Oct. 1988 at 280 seeds $\mathrm{m}^{-2}$. Plots were 12 rows and 6.1 by 1.2 m . For weed control, Propachlor [2-chloro-N-(1-methylethyl)-N-phenylacetamide] at 2.24 kg a.i. $\mathrm{ha}^{-1}$ was sprayed preemergence both years and, in 1988-89, paraquat (1, 1'-dimethyl-4,4'-bipyridinium ion) was sprayed preemergence at 0.56 kg a.i. $\mathrm{ha}^{-1}$. Emergence dates (50\% emergence) were 13 Nov. 1987 and 14 Nov. 1988.

The cover treatments, Cover Early (CE) and Cover Early Plus Late (CE+L) were created by laying a flexible transparent cover (extruded polypropylene and polyamid net; trade name Agronet, type M, Beghin Say, Kaysersberg, France) directly on the crop. A Shade treatment was created by suspending shade cloth (47\% shade, Nicolon Inc. Norcross, GA) on a wooden frame approximately 20 cm above the soil surface. Treatments were applied 22 Jan. 1988 and 24 Jan. 1989. The CE and Shade treatments were removed on 29 Mar. 1988 and 28 Mar. 1989 when Control plants had stems 1 cm long. The CE+L treatment was removed 2 weeks later.

Photosynthetically active photon flux density (PPFD) transmitted through the crop cover and through the shading material was measured hourly on two clear days, using a Model-191s quantum Sensor (Li-Cor Inc., Lincoln, NE). Air temperature above the plots was measured with 4 copper-constantan thermocouples plot $^{-1}$ placed 5 cm above the soil surface and shaded from direct sunlight. Readings for each treatment were recorded hourly by an electronic data logger (CR5 in 1988 and CR10 in 1989; Campbell Scientific, Logan, UT). Daily and 30-year mean maximum and minimum temperatures were from measurements taken at Hyslop Field Laboratory located 3 km from the plots (Fig. I.1; Tables I.1 and I.2).

The Oct.-May mean air temperature at 105 cm above the plots averaged across years was $6.5^{\circ} \mathrm{C}$ and was approximately equal to the $30-$ year mean which was $6.6^{\circ} \mathrm{C}$. However, temperatures were abnormally low during the second and third weeks following treatment application in 1989. The mean air temperature under the shade cloth was slightly less than in the Control plots. However, the major effects of shading were a decrease in diurnal fluctuation of $2.0^{\circ} \mathrm{C}$ (Table I.2) and a 54\% reduction in PPFD. Crop covers increased mean maximum and minimum temperature approximately $1^{\circ} \mathrm{C}$ and decreased incident light by 18\%.

At two weeks after the beginning of rapid elongation of stems, total phytomass from $0.1 \mathrm{~m}^{2}$ was collected from all plots. Plants in the sample were counted and separated into leaves, stems (including the crown), and flower buds. Leaves which were more than 50 percent green were measured using a LI 3100 leaf area meter (Li-Cor, Lincoln, NE). Stems originating or appearing to originate from the crown or branched less than 2 cm from root tissue were counted and referred to as primary stems. The plant parts were dried at $60^{\circ} \mathrm{C}$ to a constant weight.

For pollination, honey bee hives were placed next to the experimental plots during flowering at a density of approximately five hives ha' . At flowering, a $0.1-\mathrm{m}^{2}$ area was selected randomly in each plot and the flowers which opened by 1100 h were counted and removed each day. Visible physical damage to parts of some flowers occurred both years and apparently was caused by a maggot of a small fly identified to be in the genus Scaptomyza (M. R. Wheeler, 1990, personal communication). The number of damaged opened flowers was recorded daily. A concurrent study also addressed this insect damage and the relatively low oil yields (Fiez et al., 1991a).

After flowering was complete, the unopened flower buds in the flower-counting area were removed, counted, and added to the total flower number to give the total number of buds produced. On 15 July 1988, a $2.8 \mathrm{~m}^{2}$ area of each plot was flail-harvested (Carter Manufacturing, Brookston, IN); on 27 June 1989 , a $5.6 \mathrm{~m}^{2}$ was harvested. In both years, the plants were dried 24 hours at $38^{\circ} \mathrm{C}$, threshed (Kurt Pelz thresher, Bonn-Bad Godesberg, Germany), cleaned (Clipper cleaner; Ferrell-Ross, Saginaw, MI) and the seed dried at $60{ }^{\circ} \mathrm{C}$ to a constant weight. Two random $0.14 \mathrm{~m}^{2}$ areas were vacuumed in each flail-harvested area to determine harvest loss. In 1988, the vacuumsamples were threshed and cleaned in the same manner as the flailharvested samples. In 1989, the vacuum-samples were hand-threshed. Seed yield was determined by adding harvest loss to the flail-harvested seed. The oil content of a random sample of 1000 seeds was determined using a Bruker Minispec PC 120 pulsed nuclear magnetic resonance spectroscope equipped with an $18-\mathrm{mm}$ RTa absolute probe head and an EDM 311 program module (Bruker Spectrospin Canada Limited, Milton, Ontario).

The experimental design was a randomized block with four replications in 1987-1988 and six replications in 1988-1989. Error vari-
ances were determined to be homogeneous by use of an F-test (Snedecor and Cochran, 1980). Data for years were combined for analysis of variance (Federer, 1955) or analysis of covariance. Year was considered a fixed effect. Analysis of covariance was conducted to determine treatment significance and to adjust the measured seed weight for the effect caused by insect feeding on flowers. Seed number area ${ }^{-1}$ was calculated by dividing seed yield by the weight seed ${ }^{-1}$. Seeds $f$ lower ${ }^{-1}$ was determined by dividing seed number area ${ }^{-1}$ by the number of open flowers. Phytomass samples taken on 12 April 1988 and 11 April 1989 also were analyzed using analysis of covariance with the covariate being number of plants per $0.1 \mathrm{~m}^{2}$. Treatment means were compared using a set of non-orthogonal contrasts. The alpha level was 0.05 for all response variables and 0.10 for determining covariate significance on response variables.

Shade increased oil yield an average of $47 \%$ (Table I.3). The increase in oil yield was a result of higher seed yield (35\%) and higher oil content (8\%)(Table I.3). Seed yield, oil content, and consequently oil yield, were positively correlated with seed number area $^{-1}$ (Table I.4). Two weeks after the beginning of rapid elongation of stems, shade had produced $24 \%$ less phytomass and $28 \%$ fewer stems than the Control (Table I.5). The shade treatment had no effect on stem weight, leaf area index, and seeds per flower (Tables I. 3 and I.5). There were also $27 \%$ more open flowers in the shade. Cover Early increased seed and oil yield in both years while Cover Early Plus Late was inconsistent. In 1987-1988, CE+L increased oil yield 97\% with fewer (14\%) but heavier ( $63 \%$ ) stems, $83 \%$ more seed number area ${ }^{-1}$, and $21 \%$ higher percent oil content than the Control. Also in 1987-1988, CE+L had fewer primary stems (14\%) but heavier stem (63\%) and bud (20\%) dry weights than the Control.

Contrary to the hypothesis, correlations between phytomass 2 weeks after the beginning of rapid elongation of stems and yield were not significant. However, weight seed ${ }^{-1}$ was negatively correlated with phytomass, stem weight, and bud dry weight at removal of CE+L both years (Table I.4). But differences in weight seed ${ }^{-1}$ between treatments were small both years in comparison to the influence on seed number area ${ }^{-1}$ (Table I.3). Weight seed ${ }^{-1}$ was decreased in both years by covering, whereas the effect of shading was inconsistent between years. Seed yield improvement by all treatments was associated with fewer primary stems, more flowers that opened, and greater seed number area ${ }^{-1}$. Similar results have been reported for strawberry where early shading decreased the number of runners, but increased fruit number and total berry yield (Ferree, 1988). Apparently, when excess
numbers of stems are produced, intra-plant competition for assimilate causes cessation of development of some flower buds. Thus, environmental conditions which favor development of excess primary stems may decrease Mermaid seed and oil yields. This agrees with Krebs and Jain (1985), who used stepwise multiple regression on 12 independent plant growth characters to predict meadowfoam seed yield. They reported a negative association between seed yield and the number of basal branches plant ${ }^{-1}$, whereas the correlation between seed yield and flower number was positive. Similarly, the primary effect of $N$ fertilizer -- when applied at favorable rates and times -- on meadowfoam oil yield is through increased number of opened flowers, and consequently, increased seed number area ${ }^{-1}$ (Pearson and Jolliff, 1986b; Jolliff, et al., 1991).

In both years, seeds flower ${ }^{-1}$ was positively correlated with seed number area- ${ }^{-1}$ and oil yield. Seeds flower ${ }^{-1}$ was an important component of oil yield in a concurrent study (Fiez et. al., 1991a). It has also been shown that pollination can play an important role in determining seeds flower ${ }^{-1}$ (Jahns and Jolliff, 1990; Jahns et al., 1991). These findings support future investigations of management practices and genetic selection to reduce the number of primary stems per plant as a means of increasing the number of open flowers, and consequently increasing and stabilizing oil yield.

Table I.5. Analyses of covariance, contrasts, and adjusted treatment means for some growth parameters measured at two weeks after the beginning of rapid elongation of stems as influenced by Cover Early (CE), Cover Early Plus Late (CE+L), Shade, and Control, in 1987-1988 and 1988-1989.

Figure I.1. Mean maximum and mean minimum temperatures (approximately weekly) recorded at 5 cm above the soil surface, under transparent crop cover (CE+L), shade cloth (S), and Control (C) in 1987-1988 and 1988-1989; as compared to the $30-y e a r$ means ( 30 M ) (measured at 105 cm above the soil surface). The Cover Early treatment is included within CE+L; CE and $S$ were removed the same day.

## CHAPTER II

FLOWER PRODUCTION AND HONEY BEE DENSITY EFFECTS ON MEADOWFOAM SEED YIELD

ABSTRACT

Meadowfoam (Limnanthes alba Hartw. ex Benth. ssp. alba cv. Mermaid) is protandrous and entomophilous. Flower number and phenology, stigma receptivity, and timely honey bee pollination are highly weather-dependent and were hypothesized to cause much seed yield variation. The objective was to use a synchrony index -- an estimate of flower receptivity and pollination timing synchrony -- to relate variation in seed yield to number of open flowers and foraging honey bee (Apis mellifera L.) density. Transparent floating crop-cover and shade cloth were used to alter flower number and flower phenology. Cumulated open flowers and cumulated foraging bee density were derived from daily counts of flowers and foraging honey bees, respectively. Flower receptivity for each day was estimated using maximum air temperature for that day. Number of receptive flowers for each day was multiplied by the number of foraging bees for that day and summed for the bloom period to form cumulated synchrony index. A multiple regression model $\left(R^{2}=0.47, P=0.001\right)$ indicated a linear positive association of seeds flower ${ }^{-1}$ with cumulated foraging bee density, and a quadratic negative (within the experiment range) association with cumulated open flowers. A simple linear regression explained $87 \%(\mathrm{P}=0.001)$ of the variation in seed number area ${ }^{-1}$ by differences in cumulated synchrony index. This confirms the importance of pollination timing, foraging honey bee activity, and total number of flowers for achieving high seed and oil yield and emphasizes the need for careful management and monitoring of these variables. Yield may be increased and stabilized by consistent high levels of pollination.

## INTRODUCTION

Limnanthes alba flowers are self-compatible, protandrous, and entomophilous (Devine and Johnson, 1978; Mason, 1952). Cultivated meadowfoam flowers profusely, is indeterminate, and is pollinated primarily by honey bees (Apis mellifera L.)(Kalin, 1971). It has been speculated for several years that seed yield may be limited by inadequate pollination (Calhoun and Crane, 1978; Gentry and Miller, 1965), but no data were provided to relate pollinator foraging to seed yield. More recently, data have been reported which relate seeds flower ${ }^{-1}$ is related to measures of bee density (Jahns and Jolliff, 1990; Jahns, et al., 1991; Pearson and Jolliff, 1986a). The critical aspect of proper pollination timing also has been demonstrated in a greenhouse study. Stigmas pollinated at 48 h postanthesis produced almost 3 times as many seeds flower ${ }^{-1}$ as those pollinated at 24 and 72 h (Jahns, 1990).

In a recent field study, as bee visits increased from 1 to 11 flower ${ }^{-1}$, the seeds flower ${ }^{-1}$ increased from 1.6 to 3.3 , suggesting that multiple bee visits are required for maximum seed set (Jahns and Jolliff, 1990). In strawberry (Fragaria x ananassa Duch.), 20 to 25 visits may be required for optimal fruit set (Skrebtsova, 1957). More recent work with strawberry, however, indicates that length of visits is also important (Chagnon et al., 1989). If 11 bee visits flower ${ }^{-1}$ are required for maximum seed set in meadowfoam (Jahns and Jolliff, 1990), and 4210 flowers $\mathrm{m}^{-2}$ opened in 1 day (Pearson and Jolliff, 1986b), 46310 bee visits $\mathrm{m}^{-2}$ day ${ }^{-1}$ would be needed (at maximum bloom) to realize the potential seed set. This illustrates the high demand for adequate bee foraging at maximum bloom and the importance of matching flower opening and foraging bee activity for meadowfoam seed production. Pollination of flowers by foraging honey bees is
dependent on many things, including the number, strength, and placement of honey bee colonies, and environmental conditions, including rain, light, temperature, and wind speed (Burgett et al., 1984; Jahns et al., 1991). Further, Burgett (1976) and Pearson and Jolliff (1986b) showed that foraging honey bees can be attracted away from meadowfoam to other flowering plants. This diversion of foraging bees to other plants can occur in as few as 2 to 4 days after bee hives have been delivered to a meadowfoam field. Thus, it becomes apparent that meadowfoam flower phenology and factors influencing pollinator activity during a few critical days during the bloom period may have major impacts on meadowfoam seed yield.

To test the importance of flower production and pollinator activity and the synchronous occurrence of flower receptivity and pollinator activity on seed number area ${ }^{-1}$ it was necessary to apply treatments to cause differences in these variables. Two synthetic cloth-like materials were used to provide the needed treatments. A transparent floating crop cover was selected since it has been shown to advance flowering in strawberry (Gent, 1990). Shade cloth was also selected since it suppresses dry matter production and may influence partitioning of assimilates within crop canopies, which may alter flower production (Early et al., 1967; Egli, 1988; Hang et al., 1984). These materials were used to modify flower number and flower phenology in field-grown meadowfoam with the objectives of determining if: i. a measure of flower number and pollinator activity can be used to estimate seed set and seed yield, and ii. the estimate in seed set area ${ }^{-1}$ could be improved by adjusting for stigma receptivity and pollination timing.

#### Abstract

Field experiments were conducted at Oregon State University Schmidt Research Farm near Corvallis, Oregon (44 and $38^{\circ} \mathrm{N}, 123^{\circ}$ and 12'W) in 1987-1988 and 1988-1989 on an Amity silt loam (fine-silty, mixed, mesic Argiaquic Xeric Agialboll). Detailed methods are given elsewhere (Materials and Methods, Chapter I). Meadowfoam cv. Mermaid was planted in 15-cm rows on 1 Oct. 1987 and 6 Oct. 1988, at 279 seeds $\mathrm{m}^{-2}$. Dates of $50 \%$ emergence were 13 Nov. 1987 and 14 Nov. 1988. Three treatments and a Control were studied. The Cover Early (CE) and the Cover Early Plus Late (CE+L) treatments were created by laying a transparent floating crop cover (trade name Agronet, type $M$, Beghin Say, Kaysersberg, France) directly on the crop. The Shade treatment was created by placing shade cloth (47\% shade, Nicolon Inc., Norcross, Georgia) suspended on a wooden frame approximately 20 cm above the soil surface. Treatments were applied 22 Jan. 1988 and 24 Jan. 1989. Shade and CE treatments were removed at the beginning of rapid elongation of stems -- defined as the time when Control plants had approximately 1 stem, 1 cm in length -- which occurred on 29 Mar. 1988 and 28 Mar. 1989. The CE+L was removed 2 weeks after the beginning of rapid elongation of stems.

Honey bee hives were placed next to the experimental plots during flowering, at a density of approximately five hives ha ${ }^{-1}$. Foraging honey bee counts were made daily during flowering between 1200 and 1300 h in a marked $0.25 \mathrm{~m}^{2}$ area in each plot. That count is referred to as the foraging bee density for each day during the flowering period. All bees foraging in the marked area at the first instant of observation were counted. Cumulated foraging bee density (CBD) was the summation of daily foraging bee densities for the flowering period. A $0.1 \mathrm{~m}^{2}$ area was randomly selected in each plot to

determine number of open flowers each day. Flowers were considered open if a honey bee could physically enter the flower. Flowers open by 1100 h were removed and counted each day, and summed to generate cumulated open flowers (COF).

A regression model was used (Table II.1) to relate seeds flower ${ }^{-1}$ to COF and CBD. The equation was:

Seeds flower ${ }^{-1}(S P F)=a-b(C O F)+c(C O F)^{2}+d$ (CBD)
Where 'a' is the intercept and 'b', 'c', and 'd' are the coefficients (Table II.1). Total seed number area ${ }^{-1}$ was then calculated:

Seed number area ${ }^{-1}(S N A)=C O F \times S P F$
Substituting equation $i$ for $\operatorname{SPF}$ in ii gives:
$S N A=a(C O F)-b(C O F)^{2}+c(C O F)^{3}+d(C B D)(C O F)$,
where SNA, COF, and CBD are expressed in numbers per unit land area.
A "synchrony index" was calculated by multiplying the number of receptive flowers by the foraging bee density for the day of optimum receptivity. Cumulated synchrony index (CSI) for each treatment is the summation of daily calculated synchrony indexes. Stigma receptivity in Limnanthes alba occurs 1 to 4 days after anthesis, depending on air temperature (Guerrant, 1984; Kalin, 1971). Similar to earlier work with meadowfoam, we considered anthesis as occurring simultaneously with flower opening (Franz and Jolliff, 1989). The optimum receptivity was then estimated, using the daily maximum air temperature (Jahns, 1990; Franz, 1990). If the maximum temperature for the day the flowers opened was less than or equal to $24.4{ }^{\circ} \mathrm{C}$, the day of optimum receptivity was 2 days following flower opening; if it was greater, the optimum receptivity was the day after opening.

The experimental design was a randomized block with four replications in 1987-1988 and six replications in 1988-1989. Error variances were homogeneous (Federer, 1955) therefore, data for 1987-1988, and 1988-1989 were combined for analysis of variance. An F-test was
used to test the equality of error variances (Snedecor and Cochran, 1980). Year was considered a fixed effect. The alpha level was 0.05 for all response variables.

Considerable variation in flower phenology occurred among treatments and years (Fig. II.1, a-b). All treatments had greater cumulated open flowers than the Control (Table II.2). Foraging bee density averaged over treatments, varied between days of bloom, and was considerably larger in 1987-1988 than in 1988-1989 (Fig. II.1, cd; Table II.2). In 1987-1988, CBD varied among treatments, whereas in 1988-1989 it did not (Figure II.le-f and Table II.2). The CSI varied among treatments both years (Fig. II.1, g-h).

A multiple regression model, which included COF and CBD, predicted $47 \%\left(R^{2}=0.47\right)$ of the total variation in seeds flower ${ }^{-1}$ (Table II.1). Seeds flower ${ }^{-1}$ was linearly (positive) related with CBD and quadratically (negative within the range of experiment observation) related with COF (Table II.1; Fig. II.2). Seeds flower ${ }^{-1}$ was the highest at the lowest COF and highest CBD (Fig. II.2).

Seed number area ${ }^{-1}$ produced was a cubic function of COF and a linear function of CBD (Fig. II.3). Consequently, although seeds flower ${ }^{-1}$ decreased as flower number increased (Fig. II.2), seed number area ${ }^{-1}$ was improved when flower number increased, especially at higher levels of CBD (Fig. II.3).

Using the treatment means for each year and simple linear regression analysis, $C B D$ and COF explained 59 and $55 \%$ of the variation in seed number area ${ }^{-1}$, respectively (regressions not shown). Cumulated synchrony index, however, explained $87 \%$ of the variation in seed number area ${ }^{-1}$ produced by the treatments (Fig. II.4). A close investigation of flower phenology, foraging bee densities, and air temperature indicated that only on a few days did high foraging bee densities coincide with the days of optimum stigma receptivity (Fig. II.1, g-h). Consequently, substantially larger variations in seeds
flower ${ }^{-1}$ as a function of COF and CBD were explained when the synchrony for stigma receptivity and pollination timing were accounted for, using CSI.

Weight seed ${ }^{-1}$ was not correlated with flower number ( $x=-0.01$; $n=40$ ) or seed number area $^{-1}(r=-0.27 ; n=40)$. However, seed yield was correlated with seed number $\operatorname{area}^{-1}(\mathrm{r}=0.84 ; \mathrm{n}=40)$. Furthermore, oil content was positively correlated with seed number area ${ }^{-1}$ (r=0.56; $\mathrm{n}=40$ ), indicating that improvements in seed number area ${ }^{-1}$ will increase oil yield.

## DISCUSSION AND CONCLUSION

The importance of flower production in meadowfoam as the major yield component has been discussed in several reports (Jolliff, et al., 1991; Pearson and Jolliff, 1986b; and CHAPTER I). Results of this experiment provide strong evidence that meadowfoam seed yield is vulnerable to the synchrony of stigma receptivity and honey bee pollination. Therefore, genetic, cultural, and environmental variables which influence flower production and opening, or pollinator activity may affect the crop yield. Further research is needed to determine when CSI no longer increases seed number area- ${ }^{-1}$ or yield.

Cumulated foraging bee density was positively correlated with COF ( $r=0.46$; $n=40$ ), while bloom duration was not greatly influenced. Therefore, this correlation indicates that increasing bloom intensity increases CBD. This agrees with Ribbands' (1949) observation that profuse flowering might be advantageous for attracting foraging honey bees and improving pollination. Pearson and Jolliff (1986a) also reported a positive relationship between numbers of open flowers and foraging bee densities in meadowfoam. Proper timing and placement of honey bee colonies are critical for successful meadowfoam pollination (Burgett et al., 1984; Jahns et al., 1991). Because of the relative attractiveness of competing flowers to foraging honey bees, meadowfoam pollen collection can decline from 100\% at first placement of hives, to almost no pollen collected after 7 days (Burgett, 1976). Therefore, introducing new colonies at 3 to 5 day intervals has been recommended (Jolliff et al., 1981; Jahns et al., 1991).

In natural habitat, Limnanthes species can have a bloom period which is in a high degree of synchrony with foraging activity of an oligolectic bee Andrena (Hesperandrena) limnanthis (Thorp, 1990). Possible benefits for using native insects such as limnanthis war-
rants further investigation. Another bee species, Osmia lignaria propinqua Cresson, has also shown promise for pollinating meadowfoam (Jahns, 1990; Jahns and Jolliff, 1991). Suggested benefits of 0. 1. propinqua include reducing the effects of inclement weather on pollinator activity, and the possibility of a developing a large local population, which could be managed to synchronize foraging bee emergence with meadowfoam bloom.

Development of self-pollinating meadowfoam has been suggested (Jolliff, 1981) as a means of decreasing vulnerability to pollinator effects. Potential for development of a self-pollinating meadowfoam cultivar exists (Jolliff et al., 1984; Kalin, 1971). However, inbreeding depression has been substantial (unpublished data, 1990, New-Crops Research Project, Oregon State University), which detracts from development of such cultivars. Meadowfoam oil yield may also be increased and stabilized by increased attractiveness to foraging honey bees and by increased duration of flower receptivity.

#### Abstract

Meadowfoam (Limnanthes alba Hartw. ex Benth. ssp. alba cv. Mermaid) seed yield, and consequently oil yield, has varied considerably among years. High stable oil yield is needed to enhance commercialization. Reports in the literature indicate a negative relationship between seed yield and phytomass production. The objective of this research was to determine the association between flower production and phytomass cumulation and partitioning. Treatments of a transparent floating crop cover (Cover) and shade cloth (Shade) were used to alter phytomass production. Cover and Shade treatments were applied 22 Jan. 1988 and 24 Jan. 1989 and removed 28 Mar. 1988 and 29 Mar. 1989, respectively. Measurements of phytomass production and distribution, leaf area index, crop growth rate, and net assimilation rate were made. Flower production was not significantly correlated with total phytomass produced at two weeks after the beginning of rapid elongation of stems or at the beginning of flowering. However, flower production and seed yield were correlated with the percent of phytomass in stems at the beginning of flowering ( $r=0.76, \mathrm{n}=8$; for both correlations). Flower production and seed yield were not associated with greater partitioning to leaves. Therefore, improvement in yield might be realized by increasing flower production through manipulation of cultural practices, environment, or genetics, which would hasten partitioning to stems.

## INTRODUCTION

Meadowfoam is a herbaceous winter annual domesticated at Oregon State University (Jolliff, 1981) for its unique seed oil (Earle, et al., 1959; Nikolava-Damyanova, 1990). Seed yield has varied significantly among years. High and stable oil yield is needed to make meadowfoam a more attractive commercial crop.

Little research was found on meadowfoam growth and development. Pearson and Jolliff (1986b) reported a large variation in total above-ground dry matter (phytomass) in mid-April between the two years. Oil yield in the low-phytomass year was $181 \%$ greater than when phytomass was high, suggesting that a negative relationship exists between phytomass in mid-April and oil yield at maturity. In California, Krebs and Jain (1985) found yield of L. alba accessions to be negatively correlated with both crop growth rate and leaf area at 88 days after sowing. Native Limnanthes alba has a relatively high-risk life history/cycle strategy (Ritland and Jain, 1984) and responds quickly to resource availability (zedler, 1990). Therefore, under the mild and wet cultivated conditions of western Oregon during November through March, it is suspected that $L$. alba may tend to produce excess vegetative dry matter at the expense of seed yield.

Number of flowers has been shown to be an important yield component in meadowfoam, and the most consistent indicator of seed Yield (Krebs and Jain, 1985; Jolliff and Seddigh, 1991; Jolliff, et al., 1991; and Pearson and Jolliff, 1986b). Application of 50, 100, and 200 kg N ha - resulted in 38,72 , and $92 \%$ increases in flower production and, consequently, increased seed number area ${ }^{-1}$ (Jolliff, et al., 1991). The increased flower number was also shown to have a positive linear relationship to total dry matter produced. Krebs and Jain (1985) suggested that improvement in seed number area ${ }^{-1}$ in $L$. alba
may be possible by selection for increased number of primary stems and, thus, the number of flowers produced.

Early season control of phytomass distribution may be a key element in determining meadowfoam flower production. Therefore, the hypothesis this work was based on is that modification of early biomass production may improve meadowfoam oil yield.

The hypothesis was tested in the field by use of transparent floating crop cover (Cover), and shade cloth (Shade) treatments, which modified early phytomass distribution. Floating crop covers have been used to increase air temperatures (Hall, 1971; Shadbolt and MCCoy, 1960; Wells and Loy, 1985). In strawberry (Fragaria $x$ ananassa Duch.), time of flowering, fruit set, and fruit ripening were hastened in direct relation to the duration row covers were in place in the spring (Gent, 1990). Growth rates of cucumber [Cucumis sativus (L.)] were increased by use of covers (Wolfe et al., 1989).

Shade cloth reduces the amount of light received by a crop, suppresses dry matter production, and may influence flower production and partitioning of assimilates within crop canopies (Early et al., 1967; Egli, 1988; Hang et al., 1984).

Field experiments were conducted at Oregon State University Schmidt Research Farm ( $44^{\circ}$ and $38^{\prime}$ N, $123^{\circ}$ and $12^{\prime} \mathrm{W}$ ) in 1987-1988 and 1988-1989 on an Amity silt loam (fine-silty, mixed, mesic Argiaquic Xeric Agialboll). Mermaid meadowfoam was planted in $15-\mathrm{cm}$ rows on 1 Oct. 1987 and 6 Oct. 1988 at 280 seeds $\mathrm{m}^{-2}$. Emergence date (50\% emergence) was 13 Nov. 1987 and 14 Nov. 1988. The experimental design was a randomized block with four replications in 1987-1988 and six replications in $1988-1989$ with a plot size of 3.6 by 6.1 m . The alpha level was 0.05 for all response variables. Three treatments and a Control were studied.

The Cover Early and Cover Early Plus Late treatments were created by laying a transparent floating crop-cover (trade name Agronet, type $M$, Beghin Say, Kaysersberg, France) directly on the crop. The shade treatment was created by suspending shade cloth (47\% shade, Nicolon Inc., Norcross, Georgia) on a wooden frame approximately 20 cm above the soil surface. All treatments were applied 22 Jan. 1988 and 24 Jan. 1989. Cover Early and Shade treatments were removed at the beginning of rapid elongation of stems -determined visually, and defined as when Control-plants had approximately 1 stem 1 cm in length. Treatment removal was 29 Mar. 1988 and 28 Mar. 1989. Both years, Cover Early Plus Late was removed 2 weeks after the beginning of rapid elongation of stems. Detailed research methods and weather data were given elsewhere (Chapter I).

To evaluate dry matter accumulation and partitioning, plant samples, including abscised material, were taken at random on thirteen dates between Julian days 7 and 192 in 1987-1988. In 19881989, plant samples from $0.10-\mathrm{m}^{2}$ areas were taken on eleven dates between Julian days 24 and 173 for leaf area and dry matter
determinations. Sample size was $0.15 \mathrm{~m}^{2}$. Plants were divided into leaves (including petiole), stems (including crown), and buds plus flowers. The dry weight of leaves, stems, and flower buds plus flowers were determined. Leaf area index (LAI) was measured on 0.10$m^{2}$ portion of the sample area. Leaf area was determined using a LI 300 leaf area meter (Li-Cor, Lincoln, NE). Only leaves that were more than 50\% green (determined visually) were included in leaf area. For pollination, honey bee hives were placed next to the experimental plots during flowering at a density of approximately five hives ha ${ }^{-1}$. At flowering, a $0.1-\mathrm{m}^{2}$ area was selected randomly in each plot, and the flowers which opened by 1100 h were counted and removed each day.

Plots were flail-harvested (Carter Manufacturing, Brookston, IN) on 15 July 1988 and 27 June 1989 (Julian days 197 and 178 respectively), and dried 24 hours at $38{ }^{\circ} \mathrm{C}$ to a constant weight. Harvested areas of plots were $2.8 \mathrm{~m}^{2}$ in 1988 and $5.6 \mathrm{~m}^{2}$ in 1989. Two random $0.14 \mathrm{~m}^{2}$ areas were vacuumed in each flail-harvested area to determine harvest loss. In 1988, the vacuum-collected samples were threshed and cleaned the same as the flail-harvested samples. In 1989, the vacuum-collected samples were hand-threshed. Seed yield was determined by adding vacuumed seed to the flail-harvested seed.

Polynomial regression equations were fitted to natural
logarithm transformations of data to describe changes over time for each response variable in each treatment (Hunt, 1982). Actual measurements were used to compare treatments at selected times (Table III.1). Crop growth rate (CGR) and net assimilation rate (NAR) were derived from regression equations for dry weight and LAI (Hunt, 1982).

RESULTS

Treatment effects of Cover Early and Cover Early Plus Late were similar. Therefore, for ease of graphic interpretation only data for Cover Early (Cover), along with the Control and Shade treatment, are presented. For the majority of the growing season in 1987-1988, Cover increased phytomass whereas shading decreased it. However in 1988-1989 smaller differences in phytomass were created by covering and shading, and maximum phytomass achieved by all treatments was less (Fig. III.1a and III.1b). Averaged over years, the number of open flowers $\mathrm{m}^{-2}$ for the Control, Cover, Cover Early plus Late, and Shade were 4634, 5838, 5597, and 5821. A positive correlation ( $r=0.76, P=0.029$ ) was found between flower number and the percent of phytomass in stems at the beginning of flowering (Fig. III.2a). Seed yield was also positively correlated ( $x=0.76, P=0.028$ ) with the percent of phytomass in stems at the beginning of flowering (approx. first bloom)(Fig. III.2b, Fig. III.3e and Fig. III.3f). Flower number was not significantly correlated with any other response variable at treatment removal or the beginning of flowering (correlations not shown).

Leaf area development in the Cover and Shade treatments tended to increase and decline earlier than in the Control (Fig. III.lc and III.1d). On Julian day 46 in 1988 the Cover and Shade treatments had 41 and 7 \% higher leaf area than the Control, respectively (Table III.1). On day 51 in 1989 the Cover and Shade treatments had 138 and 152\% more leaf area than the Control, respectively. However, in both years the Cover and Shade had less leaf area than the Control later in the season (Table III.1).

Treatment effects on CGR, like phytomass, was increased by covering and decreased by shading in 1987-1988 and there were only
small differences in 1988-1989 which provided little explanation for changes in flower production (Fig. III.3a and III.3b). In both years CGR for all treatments reached its maximum near early bloom and dropped precipitously to near zero by the end of bloom.

Net assimilation rate was lower for the Cover and Shade treatments than in the Control during application of the treatments, whereas the situation was reversed during flowering (Fig. III.3c and III.3d). For all treatments and in both years, NAR was the highest at near peak bloom and decreased sharply to near zero by the end of bloom.

The percent of phytomass in stems was greater in both the Cover and Shade treatments as compared to the Control (III.3e and III.3f). This trend was first apparent after treatment removal. Phytomass distribution to stems for Cover and Shade was more than the Control by 32 and $11 \%$ on Julian day 116 in 1988 , and by 19 and $17 \%$ on Julian day 114 in 1989, respectively (Table III.1). Furthermore, phytomass distribution to buds and flowers for Cover and Shade treatments was higher than the Control by 33 and $35 \%$ on Julian day 130 in 1988, and by 18 and 22 on Julian day 128 in 1989, respectively (Table III.1). Partitioning to buds plus seeds also was increased for the covered and shaded treatments than the Control (Fig. III.3e and III.3f).

The increased partitioning to stems and buds plus seeds by the Cover and Shade treatments was at the expense of leaf production (Fig. III.3e and III.3f). Phytomass distribution to leaves for Cover and Shade was 21 and 9\% less than the Control on Julian day 116 in 1988, and 15 and $18 \%$ less on Julian day 114 in 1989, respectively (Table III.1).

At the beginning of flowering, percent phytomass in stem tissue was the only measured variable associated with treatment induced increases in flower number. One attribute of stem tissue is carbohydrate storage. In a concurrent study (Fiez, et al., 1991b) stems contained 354 and $94 \%$ more ethanol soluble carbohydrates than leaves or flowers, respectively. Also, the level of potentially remobilizable carbohydrate was positively associated with seed yield. Thus, the increase in flowers in this study may have been the result of more potentially remobilizable carbohydrate in stems to support flower bud development.

Cover and Shade reduced the number of primary stems plant ${ }^{-1}$ at 2 weeks after the beginning of rapid elongation of stems (time of $C E+L$ removal) (Chapter I). Perhaps the Cover and Shade treatments had early initiation of fewer stems plant ${ }^{-1}$, which apparently were stronger sinks than competing stems (or stem primordia), thereby limiting the growth of other axillary stem primordia and providing fewer more robust stems. Larger diameter stems were visually apparent in the Shade treatment. Also visually apparent at time of treatment removal was increased elongation of stems by the Cover and Shade treatments.

In Limnanthes alba, seed yield has been shown, by a stepwise multiple regression model, to be associated with fewer basal stems, supporting our results (Krebs and Jain, 1985). However, in the same experiment simple correlations of flower number was positively associated with basal branches plant ${ }^{-1}$, which is not consistent with our results. Krebs and Jain (1985) measured genetic variation between Limnanthes alba genotypes whereas, in this study shading and covering induced variation with one cultivar, which may provide
different results. Pierce and Jain (1976) also reported a positive association of basal branches plant ${ }^{-1}$ and flower number of meadowfoam plants grown in pots in the phytotron. However, flower production of single plants grown in pots may react considerably different as compared to solid stand in the field.

Native Limnanthes alba has a relatively high-risk life history/cycle strategy (Ritland and Jain, 1984), and responds quickly to resource availability (Zedler, 1990). The result can be an excess commitment to development of leaf mass and numbers of primary stems if resources are available early in the season. Then, increased intra-plant competition may cause some flower buds to senesce resulting in fewer open flowers. The mild and wet climate of western Oregon with more available resources than in native meadowfoam habitat may frequently result in growth over-commitment. High nitrogen fertility might be expected to accentuate such a tendency (Jolliff and Seddigh, 1991).

Observations in the laboratory indicated that Mermaid seedlings have little or no juvenility and may be initiated soon after germination. We have dissected plants from the field as early as December and found reproductive buds. Numerous primordia form on meadowfoam crowns. These buds often develop during winter months if temperatures are mild. Usually, growth of these buds is increased by late February. Ultimately this primordia would develop into the number of buds produced. The total number of flower buds produced in this study was not influenced and numbers were low in comparison to the number of developed flowers in high yielding years (Chapter I) (unpublished data, 1990, New Crop Project, Oregon State University). This supports a hypothesis that determination of the number of flower buds occurred early in plant development and before shading and covering had a major impact on plant parameters in this
experiment. Further research is needed to confirm the timing of reproductive initiation in meadowfoam and its influence on flower production.

In conclusion, meadowfoam flower production and seed yield may be increased by avoiding over-commitment to production of leaf mass and excessive number of primary stems. Stored carbohydrates in the stems of the shade and cover treatments possibly provided nutritional support for the higher rate of flower bud development compared to the Control. Genetic and management manipulation to avoid overcommitment may be fruitful.

APPENDIX

Appendix Figure I.1. Pictures of shade cloth (black) and transparent floating crop cover (white) during application.

Appendix Figure I.2. Pictures of Mermaid meadowfoam plants with leaves removed. Top picture shows differences in stem elongation of single plants from the Control as influenced by Cover Early (Agronet 67 Day), Cover Early Plus Late (Agronet 81 Day), and Shade on 11 April 1988. Bottom picture contrasts $0.1 \mathrm{~m}^{2}$ samples from the Control with Cover Early (Agronet 63 Day), Cover Early Plus Late (Agronet 71 Day), and Shade on 10 April 1989.

Appendix Table I.1. Average, maximum and minimum temperatures ( ${ }^{\circ} \mathrm{C}$ ) from Julian day 7 to 102 for the Control (C) and during treatment application for Cover Early Plus Late (CE+L) and Shade (S) in 1988.

Appendix I.3. Accumulated Growing Degree Days (GDD) from emergence to physiological maturity for the Control (C), Cover Early (CE), Cover Early Plus Late (CE+L), and Shade (S) in 1987-1988 and 19881989. If mean temperature for the day was $>0{ }^{\circ} \mathrm{C}$ then: GDD $=$ Max. temp + Min. temp / 2. If mean temperature for day was $<0$ ${ }^{\circ} \mathrm{C}$ then GDD $=0$.

Appendix I.4. Data collected during growth analysis in 1988. Measurements include: julian days; block (Blk); treatment (Trt); number of plants in $0.1-\mathrm{m}^{2}$ sampling area (converted to meter ${ }^{2}$ ); total above-ground dry weight (phytomass), leaf area index (LAI), dry leaf, stem, bud (without seed), and seed weights, and the number of primary stems per area.

| Julian Days | Blk | $\begin{gathered} \text { Trt } \\ t \end{gathered}$ | $\begin{aligned} & \text { no. } \\ & \text { plts } \\ & \# \mathrm{~m}^{-2} \end{aligned}$ | $\begin{aligned} & \text { phyto- } \\ & \text { mass } \\ & { }^{9} \mathrm{~m}^{-2} \end{aligned}$ | leaf area index LAI | leaf x wt. | stem wt. <br> --- $g$ |  | seed wt. $\qquad$ | prim. stems \# $\mathrm{m}^{-2}$ |

Appendix I.5. Data collected during growth analysis in 1989.
Measurements include: julian days; block (Blk); treatment (trt); number of plants in $0.1-\mathrm{m}^{2}$ sampling area (converted to meter ${ }^{2}$ ); total above-ground dry weight (phytomass), leaf area index (LAI), dry leaf, stem, bud (without seed), and seed weights, and the number of primary stems per area.

| 159 | 33 | 31 | 24 | 27 | 4487 | 6260 | 4810 | 5322 |

Appendix I.8. Mean (of four replications) seed yield and total above-ground dry matter produced (Phytomass) by meadowfoam lines 75765 and 75-729 as influenced by covering and shading in 1987-1988.

| Treatment | Seed Yield | Phytomass at maturity |
| :---: | :---: | :---: |
| 765 |  |  |
| Control | 692 | 7153 |
| Cover Early | 1120 | 7893 |
| Cover Early Plus Late | 1214 | 8668 |
| Shade | 1049 | 7493 |
| 729 |  |  |
| Control | 528 | 5704 |
| Cover Early | 622 | 7568 |
| Cover Early Plus Late | 785 | 7726 |
| Shade | 771 | 7282 |

Appendix I.9. Mean (of four replications) seed yield and total above-ground dry matter produced (Phytomass) by 85-765 as influenced by covering from December 2 to the begining of rapid elongation of stems (CDE), from December 2 to 2 weeks after the begining of rapid elongation of stems (CDE+L) and covering for two weeks (CDL) from the begining of rapid elongation of stems in 1987-1988.

| Treatment | Seed Yield | Phytomass |
| :--- | :---: | :---: |
| Control | 692 | 7153 |
| CDE | 1011 | 7997 |
| CDL $\dagger$ | 595 | 6896 |
| $C D E+L$ | 1196 | 8032 |

$\dagger$ This treatment appeared to have the most extensive insect
(Scaptomyza) damage in all of the 1987-1988 experiments.

Appendix I.10. Total above-ground dry matter (Phytomass) and harvest index at harvest for Mermaid meadowfoam as influenced by treatments in 1987-1988 and 1988-1989.

| Treatment | Phytomass | Harvest Index |
| :--- | :--- | :--- |
| 1987-1988 | Mg ha |  |
| Control | 6.84 | 0.080 |
| Cover Early | 7.09 | 0.101 |
| Cover Early Plus Late | 7.55 | 0.120 |
| Shade | 7.43 | 0.109 |
| L.S.D. (0.05) | 0.443 | 0.0252 |
| 1988-1989 | 5.45 | 0.109 |
| Control | 5.68 | 0.119 |
| Cover Early | $4.93 \dagger$ | 0.128 |
| Cover Early Plus Late | 0.137 |  |
| Shade | 5.54 | 0.023 |
| L.S.D. (0.05) | 0.778 |  |

$\dagger$ In 1988-1989, the standard deviation was two times larger for Cover Early Plus Late than any other treatment in both years.

Appendix Table I.11. Polynomial regression model coefficients describing the relationship of $\ln$ (phytomass) $\ln (l e a f$ area index), $\ln$ (percent leaf tissue), (ln(percent stem tissue), and $\ln$ (percent bud+seed tissue) of Mermaid meadowfoam and Julian days (JD) for Control, Cover Early and Shade treatments in 1987-1988.
