4 Abstract

5  
6 Western diets are high in fat and sucrose and can influence behavior and gut microbiota. There  
7 is growing evidence that altering the microbiome can influence the brain and behavior. This  
8 study was designed to determine whether diet-induced changes in the gut microbiota could  
9 contribute to alterations in anxiety, memory or cognitive flexibility. Two month old, male C57BL/6  
10 mice were randomly assigned high fat (42% fat, 43% carbohydrate (CHO), high sucrose (12%  
11 fat, 70% CHO (primarily sucrose) or normal chow (13% kcal fat, 62% CHO) diets. Fecal  
12 microbiome analysis, step-down latency, novel object and novel location tasks were performed  
13 prior to and two weeks after diet change. Water maze testing for long- and short-term memory  
14 and cognitive flexibility was conducted during weeks 5-6 post-diet change. Some similarities in  
15 alterations in the microbiome were seen in both the high fat and high sucrose diets (e.g.,  
16 increased Clostridiales), as compared to the normal diet, but the percentage decreases in  
17 Bacteroidales were greater in the high sucrose diet mice. Lactobacillales was only significantly  
18 increased in the high sucrose diet group and Erysipelotrichales was only significantly affected  
19 by the high fat diet. The high sucrose diet group was significantly impaired in early development  
20 of a spatial bias for long-term memory, short-term memory and reversal training, compared to  
21 mice on normal diet. An increased focus on the former platform position was seen in both high  
22 sucrose and high fat groups during the reversal probe trials. There was no significant effect of  
23 diet on step-down, exploration or novel recognitions. Higher percentages of Clostridiales and  
24 lower expression of Bacteroidales in high-energy diets were related to the poorer cognitive  
25 flexibility in the reversal trials. These results suggest that changes in the microbiome may  
26 contribute to cognitive changes associated with eating a Western diet.

7  
8  
9 The Western diet contributes to many chronic, diet-related illnesses in the United States,  
10 including the obesity epidemic (Cordain et al., 2005). Western diets are typically high in fat and  
11 simple carbohydrates (Cordain et al., 2005). Higher intake of fats and refined sugars are  
12 associated with deficits in cognitive flexibility and hippocampal-dependent memory in humans  
13 (Kalmijn, 2000, Francis and Stevenson, 2011) and an increase in the incidence of Alzheimer's  
14 disease (Pasinetti, 2002). There is evidence of a vicious cycle of hippocampal damage  
15 associated with a Western diet, followed by increased energy intake (Kanoski and Davidson,  
16 2011, Kanoski, 2012). It is not clear whether these effects are due to direct or indirect influences  
17 of alternative energy sources on the brain.

25  
26  
27

28 Diets high in fat and/or sugar alter the microbiome of the gut (Li et al., 2009, Turnbaugh et  
29 al., 2009). Western diets in rodents are associated with increases in microbes in the phylum  
30 Firmacutes and decreases in Bacteriodetes (Turnbaugh et al., 2009, Ohland et al., 2013,  
31 Daulatzai, 2014, Patterson et al., 2014). Obese mice with a leptin mutation and obese people  
32 also show similar alterations in prevalence of these microbial phyla, compared to their lean  
33 counterparts (Ley et al., 2005, Ley et al., 2006b).  
34  
35  
36  
37  
38  
39  
40  
41

42 The gut microbiome in humans consists of approximately 100 trillion microorganisms (Ley et  
43 al., 2006a). Firmacutes and Bacteriodetes make up the majority of this population in the mouse  
44 and human gut (Ley et al., 2005, Ley et al., 2006a, Ley et al., 2008, Turnbaugh et al., 2009).  
45 Firmacutes are predominantly gram-positive bacteria, and include three classes: Bacilli,  
46 Clostridia and Erysipelotrichia (Ludwig et al., 2009). Bacteriodetes are gram-negative, anaerobic,  
47 rod-shaped bacteria, found in the environment and guts of animals (Eckburg et al., 2005). In  
48 recent years it has become increasingly clear that the intestinal bacteria impact main functions  
49 in the body, including maturation of the immune system and metabolic processes. In fact, the  
50

1  
2  
3  
4 effect of the composition of the microbiome in obesity is a good example of the importance of  
5  
6 the bi-directional communication between the host and the resident microflora.  
7

8  
9 There is increasing evidence for an influence of the microbiome on the brain and behavior  
10 (Collins et al., 2012). Probiotics and/or antimicrobials can alter memory, anxiety and long-term  
11  
12 potentiation and hippocampal and amygdala levels of brain-derived neurotrophic factor (BDNF) in  
13  
14 animals (Bercik et al., 2011, Collins et al., 2012, Davari et al., 2013, Hsiao et al., 2013).  
15  
16 Fermented milk with a probiotic reduced activation of brain regions associated with emotional  
17  
18 responses in humans (Tillisch et al., 2013). The probiotic contained primarily bacteria from the  
19  
20 Firmicutes; Bacilli; Lactobacillales order (Ludwig et al., 2009, Tillisch et al., 2013). A lean ground  
21  
22 beef diet promoted greater bacterial diversity in the intestine and improved working and  
23  
24 reference memory (Li et al., 2009). The current study was designed to determine whether  
25  
26 specific changes within the microbiome could account for alterations in cognitive functions.  
27  
28 High-energy diets were used to manipulate the gut microbiome (Li et al., 2009, Turnbaugh et al.,  
29  
30 2009).

## 38 2. EXPERIMENTAL PROCEDURES

### 39 2.1. Animals

40  
41  
42 Eighteen male C57BL/6J mice (8 weeks of age) were purchased from JAX Laboratories (Bar  
43  
44 Harbor, ME). Mice were housed at Oregon State University's animal facilities under a 12/12  
45  
46 hour light/dark cycle with food and water available on an *ad libitum* basis. Three siblings were  
47  
48 housed together in each cage for the first 2 weeks on a control chow diet (normal; Table 1). The  
49  
50 mice were rotated between uncleaned cages for 2 weeks, until all the mice had been exposed  
51  
52 similarly, in order to establish uniform microbiome baseline. Mice were then individually housed  
53  
54 and, within each trio, were randomly assigned to a 42% fat diet (high fat), 70% carbohydrate  
55  
56 diet (66% sucrose; high sucrose) or normal diet group (Table 1). Fecal collections for

1  
2  
3  
4 microbiome analysis and step-down latency and novel object and novel location tasks were  
5  
6 performed prior to the diet change and were repeated two weeks after the diet change. Water  
7  
8 maze testing for long- and short-term memory and cognitive flexibility was conducted during  
9  
10 weeks 5 and 6 post-diet change.

14

## 15 2.2 Microbiome analysis

### 16 2.2.1. DNA extraction and 16S sequencing.

17  
18 Genomic DNA was extracted from approximately 100 mg of fecal sample using the Qiagen  
19  
20 QIAamp DNA Stool Mini Kit (Qiagen, Valencia, CA, USA) according to manufacturer's  
21  
22 instructions with the following changes: during the step 2 vortex step manual homogenization  
23  
24 with a sterile pestle was performed to break up the sample, in step 3 the samples were heated  
25  
26 to 94 degrees for 5 minutes, and step 6 vortexing was done for 4 minutes. All samples were  
27  
28 diluted to 3ng/ul and 5 ul of template went into each DNA amplification. Custom Lib-L Forward  
29  
30 Primer A primers with unique MID barcodes, and Custom Lib-L Primer B primers with no MID,  
31  
32 were designed to amplify the V3 and V4 regions of the 16S rRNA bacterial gene from each  
33  
34 individual sample for sequencing.  
35

51  
52  
53 The barcoded 16S amplicons were sequenced using the Roche 454 GS Jr sequencing  
54  
55 platform at the Oregon State University Center for Genome Research and Biocomputing  
56  
57 (Corvallis, OR). A total of 36 mouse fecal microbiota samples were sequenced and analyzed.  
58  
59 We obtained a total of 196,297 reads from the run with a mean of 5453 reads per sample.  
60

2  
3  
4  
5  
6  
7 2.2.2. Analysis of 16S rRNA sequence.

8  
9 The raw sequence data were demultiplexed, quality filtered and analyzed further using the  
10 QIIME software for comparison and analysis of microbial communities (Caporaso et al., 2010).  
11  
12 The sequences were clustered into operational taxonomic units (OTUs) at 97% sequence  
13 similarity using the uclust method against the Greengenes database (McDonald et al., 2012).  
14  
15 The constructed OTU tables were then used to determine the relative percentage of each  
16  
17 bacteria for each sample. The phylogeny based UniFrac distance metric as part of the QIIME  
18  
19 package was then used to investigate the differences in the microbial communities.  
20  
21  
22  
23  
24  
25

26 2.3. Behavioral testing

27  
28 2.3.1. Step-down latency

29  
30 The step-down latency task was conducted, as described by Anisman and coworkers  
31 (Anisman et al., 2001), one week prior to the diet change and two weeks after the diet change.  
32  
33 Briefly, mice were placed on a platform (12.5 X 8.5 cm) elevated 4 cm from a metal surgical  
34  
35 table in a dimly lit room. The latency to step down off of the platform (all four paws on the table)  
36  
37 was recorded. Three trials (5 minute maximum) were conducted with a 1-minute inter-trial  
38  
39 interval. Two different rooms were used and a block design was utilized for animals to be tested  
40  
41 in different rooms pre- versus post-diet change.  
42  
43  
44  
45  
46  
47

48  
49 2.3.2 Novel object/location recognition

50  
51 Novel object recognition and change of object location recognition tasks were based on  
52  
53 procedures used by Hohmann, et al. (Hohmann et al., 2007), with some modifications. The  
54  
55 arenas consisted of plastic boxes (12"W X 18"D X 10"H). The objects and arenas were made of  
56  
57 glass or plastic and were cleaned with 70% ethanol between sessions.  
58  
59

60 There were a total of 8 sessions over 3 days. Each session was 5 minutes in duration.  
61  
62

1  
2  
3  
4 Session 1: habituation to an empty arena, 7 minute break, Session 2: exploration of 5 objects in  
5  
6 a training location pattern, 1 hour break, Session 3: Novel object test (1 of the 5 objects was  
7  
8 replaced by a novel object), 23 hour break, Session 4: Novel object test (another of the 5  
9  
10 objects was replaced by a new object), 7 minute break, Sessions 5 & 6: Continued training of  
11  
12 location pattern, 1 hour break, Session 7: Two objects were moved to new locations, 23 hour  
13  
14 break, Session 8: Two other objects were moved to new location. The habituation trial was also  
15  
16 used to assess open field behavior; the trial was tracked and analyzed for % time in center  
17  
18 (area defined as 10 cm from each wall), exploration distance traveled and speed with the use of  
19  
20 SMART tracking system (San Diego Instruments, San Diego, CA). For novel object and location  
21  
22 tasks, exploration time for each object was obtained by manual timing for Sessions 2-4 and 6-8  
23  
24 and was expressed as a percent of the total exploration time for a single object. The  
25  
26 explorations times of the 2 moved objects were averaged to give a mean exploration time per  
27  
28 object.  
29  
30  
31  
32  
33  
34

### 35 2.3.3 Morris water maze - Memory and cognitive flexibility

36  
37 Mice were acclimated to the water maze for 2 days prior to place training, which consisted of  
38  
39 each animal swimming for 60 seconds in the tank without the platform and then being trained to  
40  
41 remain on the platform for 30 seconds each day. Spatial long- and delayed short-term memory,  
42  
43 cognitive flexibility and associative memory were assessed using the Morris water maze, as  
44  
45 described previously with some modifications (Magnusson et al., 2003b, Das et al., 2012b).  
46  
47 Briefly, following acclimation, mice underwent 4 days of long-term spatial memory testing and  
48  
49 one day of reversal task, in order to assess cognitive flexibility (Das et al., 2012b). The mice  
50  
51 underwent place training for long-term memory for 8 trials per day for 4 days, with a 2-minute  
52  
53 inter-trial interval. The platform remained in the same quadrant (SE) for all the place platform  
54  
55 trials. During the trials for place training, the mice were placed in the tank, facing the wall of the  
56  
57 tank, and were allowed to search for the platform for 60 seconds. They remained on the  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 platform for 30 seconds before being removed to their cages for 2 minutes. Entry points were  
5  
6 along the wall in the middle of the quadrants that did not contain the platform and were varied  
7  
8 between trials within each day. There was a 90 minute break after the first 4 place trials of each  
9  
10 day and a one hour break after the 8th trial of each day, followed by a probe trial, which was  
11  
12 designed to assess the animal's memory for the platform location (Gallagher et al., 1993). The  
13  
14 platform was not present during the probe trial and the animal was allowed to search for 30  
15  
16 seconds. Reversal trials were used to assess cognitive flexibility (Das et al., 2012b). One day  
17  
18 following long-term memory training, the platform was moved to the opposite quadrant (NW)  
19  
20 and 8 reversal trials and one reversal probe trial were conducted as described above.  
21  
22  
23

24 A delayed short-term spatial memory task was then performed (Magnusson et al., 2003a).  
25  
26 The task consisted of two daily sessions of 4 place trials each for 4 days. The platform position  
27  
28 changed for each session. Sessions consisted of a naïve trial, followed by a trial after a 10-  
29  
30 minute delay and 2 more trials at 30-second delays (not used for evaluation). Trials consisted of  
31  
32 60 seconds maximum in the water searching for the platform and 30 seconds on the platform.  
33  
34 Following the delayed short-term spatial memory task, an associative (control) memory task  
35  
36 (Das et al., 2012a) was employed to test motivation, visual acuity, and physical ability for  
37  
38 memory testing.  
39  
40  
41  
42  
43

#### 44 2.4. Data Analysis

45  
46 Bacterial orders and genera with averages of <.01 percent within all diet groups and  
47  
48 sequences that couldn't be assigned to a phylum were eliminated for further analysis. The  
49  
50 percent of microbiome was recalculated as a percentage of the remaining taxa. Body weight,  
51  
52 food consumption and percent of microbiome were analyzed by two-way ANOVA, followed by  
53  
54 post-hoc analysis with Tukey's correction for multiple comparisons (treating all bacterial  
55  
56 comparisons as one family) with Prism software (Graphpad Software, Inc., [www.graphpad.com](http://www.graphpad.com)).  
57  
58

59 Data for water maze testing were analyzed as described earlier with a few modifications  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 (Das and Magnusson, 2008). Briefly, the distance of the animal from the platform was measured  
5  
6 every 0.2 second by the computer for the whole duration of the trial. Cumulative proximity was  
7  
8 calculated by adding together the distance calculated at each 0.2-second interval. Correction for  
9  
10 start position was performed using a macro in Excel software (Microsoft Corp., Seattle). A  
11  
12 cumulative proximity measurement for the ideal path was calculated by this macro, with the use  
13  
14 of starting position, average swim speed and platform position. This cumulative proximity  
15  
16 measure for the ideal path was subtracted from the cumulative proximity score for the whole  
17  
18 track to obtain the corrected cumulative proximity scores for the place, reversal, short-term  
19  
20 memory and cued control trials. For the probe trials, the corrected cumulative proximity score for  
21  
22 the trial was divided by the corrected sample number to obtain a corrected average proximity  
23  
24 score. Statistical analysis for behavioral testing was performed by repeated measures ANOVA  
25  
26 (diet X trial (X session)) or (diet X Pre- vs. Post-diet), followed by Fisher's protected LSD where  
27  
28 applicable, with the use of Statview software (SAS Institute, Inc., Cary, N.C.). For novel object  
29  
30 recognition, performance compared to a chance level of 20% exploration was analyzed with  
31  
32 one-sample t-tests. Correlational analysis was performed using linear regression analysis with  
33  
34 Prism software. A p-value cutoff of .01 was used to determine significance.

### 44 3. RESULTS

#### 45 3.1 Body weight and food consumption

46  
47 The effects of the high-energy diets on weight gain and food consumption were monitored  
48  
49 throughout the experiment. There was a significant main effect of Time ( $F(5,75)=66$ ,  $p < .0001$ )  
50  
51 and a significant Time X Diet interaction ( $F(10,75)=7.5$ ,  $p < .0001$ ), but no main effect of Diet  
52  
53 ( $F(2,15)=.56$ ,  $p=.58$ ) on body weight (Fig. 1A). The mice on the high fat diet weighed  
54  
55 significantly more than those on the high sucrose diet ( $p < .01$ ), but only at 5 weeks post-diet  
56  
57 change (Fig. 1A). There was a significant main effect of Diet ( $F(2,15)=8.5$ ,  $p=.004$ ) and Time  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 (F(4,60)=54,  $p < .0001$ ) on changes in body weight from before the diet change (Pre-diet; Fig.  
5  
6 1B). Mice on the high fat diet gained more weight after the diet change than both mice on  
7  
8 normal ( $p < .05$ ) and high sucrose ( $p < .01$ ) diets when data was collapsed across weighings (Fig.  
9  
10 1B). There was a significant main effect of Diet (F(2,15)=31,  $p < .0001$ ) and Time (F(4,60)=7.2,  $p$   
11  
12  $< .0001$ ) on average daily food consumption (kcal/day; Fig. 1C). Mice that remained on the chow  
13  
14 diet (Normal) consumed more than both those on the high fat and high sucrose diets ( $p < .0001$ ;  
15  
16 Fig. 1C) when data was collapsed across weighings.  
17  
18  
19  
20  
21

### 22 3.2 Microbiome changes

23  
24 Feces were examined prior to the diet change in order to assess the efficacy of the cage  
25  
26 rotations for normalizing the microbiome between diet assignment groups. There was a  
27  
28 significant main effect of Bacterial Order (F (9,150) = 968.6,  $p < .0001$ ), but no significant  
29  
30 interaction between Pre-diet Assignment (Fig. 2; A,B, & C) and Bacterial Order (F (18,150) =  
31  
32 .06,  $p > .99$ ) in percent of the microbiome represented by each order before the diet change (Fig.  
33  
34 2 (Pre-diet change)). High-energy diets were used in this study as a method to alter the gut  
35  
36 microbiome (Li et al., 2009, Turnbaugh et al., 2009). In order to verify the effects of diet on the  
37  
38 microbiome, fecal 16S RNA was also examined 2 weeks after the diet change. Order level  
39  
40 analysis of bacteria was used initially to screen for diet effects and later for correlations with  
41  
42 behavior. There was a significant main effect of Bacterial Order (F (9,150) = 625.8,  $p < .0001$ )  
43  
44 and a significant interaction between Diet and Bacterial Order (F (18,150) = 74.55  $p < .0001$ ) in  
45  
46 percent of the microbiome represented by each order after the diet change (Fig. 2 (Post-diet  
47  
48 change); Table 2). Mice that remained on the normal diet post-diet change had a larger  
49  
50 percentage of the microbiome as Bacteroidales than those on high fat diet, which had a  
51  
52 significantly higher percentage than the high sucrose group ( $p < .0001$ ; Fig. 2; Table 2). The high  
53  
54 sucrose animals had a higher percentage of Lactobacillales than both the normal ( $p < .0001$ ) and  
55  
56 high fat ( $p < .05$ ) diet groups (Fig. 2; Table 2). Both the high fat and high sucrose groups had  
57  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 larger percentages of the microbiome represented by Clostridiales than normal ( $p < .0001$ ) and  
5  
6 the high fat group's percentage of Erysipelothrichales was higher than normal ( $p < .05$ ; Fig. 2;  
7  
8 Table 2). Tenericutes; Mollicutes; Anaeroplasmatales was only found in the mice on the normal  
9  
10 diet (Table 2).  
11

12  
13 In order to determine whether all identified bacteria within an order were affected by diet  
14  
15 similarly, analysis was also performed at the genus level. There was a significant main effect of  
16  
17 Bacterial Genera ( $F(56,840) = 235.8, p < .0001$ ) and a significant interaction between Diet and  
18  
19 Bacterial Genera ( $F(112,840) = 30.35, p < .0001$ ) in percent of the microbiome represented by  
20  
21 each genera (Table 2). Three genera of Bacteroidiales showed significantly lower and two of  
22  
23 Clostridiales showed significantly higher percentages in both the high fat and high sucrose  
24  
25 groups, as compared to the mice remaining on normal diet (Table 2). The mice on the high  
26  
27 sucrose diet had higher percentages of Lactobacillus and Lactococcus than those on normal  
28  
29 diet ( $p < .001-.0001$ ). Lactobacillales; Enterococcus was only found in the high sucrose diet  
30  
31 group (Table 2).  
32

34  
35  
36  
37

### 38 3.3 Step-down latency and open field exploration

39  
40 In order to ultimately address the hypothesis that specific changes in the microbiota can  
41  
42 influence behavior, the effects of diet on anxiety in this study were examined with a simple step-  
43  
44 down latency task and open field exploration. There was no significant effect of Diet  
45  
46 ( $F(2,15) = .09, p = .92$ ), but a significant effect of Session ( $F(1,15) = 11.4, p = .004$ ) on step-down  
47  
48 latency (Fig. 3A). On average, mice had lower latencies after the diet change than before, when  
49  
50 data was collapsed across diet groups (Fig. 3A). During the habituation trial for the novel object  
51  
52 and location tasks, there was a near significant effect of Diet ( $F(2,15) = 3.4, p = .06$ ) and a  
53  
54 significant effect of Session ( $F(1,15) = 44, p < .0001$ ) on percent time spent in the center of the  
55  
56 open field (Fig. 3B). Averaged across diet groups, mice spent a larger percentage of time in the  
57  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 center following the diet change than before (Fig. 3B). There was no effect of Diet on the path  
5  
6 length or average speed during open field exploration post-diet change ( $p=.88-.89$ ; Fig. 3-C,D).  
7  
8  
9

### 10 3.4 Novel object and location recognition

11  
12  
13 Five objects were used to assess the effects of diet on recognition memory for objects and  
14  
15 spatial alterations of objects. There was no significant effect of Diet ( $p=.13-.79$ ) or pre- vs. post-  
16  
17 diet change Session ( $p=.57-.99$ ) on novel object or novel location percent of exploration time for  
18  
19 either 1 hour or 24 hours post-familiarization (Fig. 3E-H). For novel object recognition, mice  
20  
21 performed above chance during the 1 hour delay session after the diet change (Fig. 3E;  $p=.026$ )  
22  
23 and pre- and post-diet change in the 24 hour delay session (Fig. 3F;  $p=.0007-.036$ ) when data  
24  
25 were collapsed across diet groups. Exploration of objects that changed location did not occur  
26  
27 above chance (Fig. 3G,H;  $p=.2-.3$ ).  
28  
29  
30  
31  
32

### 33 3.5 Morris water maze - Memory and cognitive flexibility

34  
35 Place trials, with the platform present in the same location, in the Morris water maze were  
36  
37 used to examine the effects of diet and associated microbial changes on acquisition of long-  
38  
39 term memory. There was no significant effect of Diet ( $F(2,15)=.15$ ,  $p=.86$ ), but a significant  
40  
41 effect of blocks of four place trials ( $F(7,105)=27$ ,  $p <.0001$ ) on cumulative proximity for long-term  
42  
43 memory in the water maze (Fig. 4A). There was a significant reduction in cumulative proximity  
44  
45 between blocks 1 and 8 of place trials ( $p<.0001$ ; Fig. 4A), when data was collapsed across diet  
46  
47 groups.  
48  
49

50  
51 Probe trials, with the platform absent, were used to analyze the development of a spatial  
52  
53 bias, as another measure of long-term memory. There was no main effect of Diet ( $F(2,15)=.21$ ,  
54  
55  $p=.81$ ), but there was a significant interaction between Diet and Trial ( $F(8,60)=2.2$ ,  $p =.04$ ) and a  
56  
57 significant main effect of Trial ( $F(4,60)=16.6$ ,  $p <.0001$ ) on average proximity in the probe trials  
58  
59 for long-term memory (Fig. 4B). In probe trial 1, mice on the high sucrose diet had significantly  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 higher average proximities than those on the normal diet ( $p=.04$ ), but in probe trial 4, the mice  
5  
6 on the high sucrose diet had a near significantly lower average proximity than the normal diet  
7  
8 group ( $p=.07$ ; Fig. 4B). Lower proximity scores are indicative of a more accurate search for the  
9  
10 platform. There was a significant reduction in average proximity between probe trials 0 and 4  
11  
12 ( $p<.0001$ ; Fig. 4B), when data was collapsed across diet groups.

15 Reversal trials, with the platform moved to the opposite quadrant, were used to assess  
16  
17 cognitive flexibility; i.e., an animal's ability to adapt to changing conditions. There was no overall  
18  
19 effect of Diet ( $F(2,15)=2.6$ ,  $p=.11$ ) on cumulative proximity to the new platform location in the  
20  
21 reversal trials, but the high sucrose group had higher cumulative proximity than the normal mice  
22  
23 ( $p=.04$ ; Fig. 4C). There was no significant difference between diet groups in average proximity  
24  
25 to the new platform location during the reversal probe trial ( $F(2,15)=.53$ ,  $p=.60$ ), but there was a  
26  
27 significant effect of Diet ( $F(2,15)=6$ ,  $p=.01$ ) on proximity to the old platform location during the  
28  
29 same trial (Fig. 4D). Both the high fat ( $p=.006$ ) and high sucrose ( $p=.015$ ) groups spent more  
30  
31 time closer to the old platform location than the normal diet group (Fig. 4D). There were no  
32  
33 differences between diet groups in swim speed in either the long-term memory or reversal trials  
34  
35 ( $p=.5-.82$ ; not shown).

40 The water maze was also used to test delayed short-term memory by analyzing the  
41  
42 difference between a naive and 10 minute delayed trial across multiple sessions. There was no  
43  
44 significant main effect of Diet ( $F(2,29)=.71$ ,  $p=.50$ ), but a near significant effect of Trial (naive vs.  
45  
46 10 min delay trials;  $F(2,29)=3.6$ ,  $p=.066$ ) on cumulative proximity in the delayed short-term  
47  
48 memory task (Fig. 5A-D). The mice on the normal diet, however, showed a significantly larger  
49  
50 difference between the naive and 10 minute delay trial than the mice eating high sucrose feed  
51  
52 ( $p=.04$ ; Fig. 5E). There was no significant effect of Diet ( $F(2,15)=.14$ ,  $p=.87$ ) on the associative  
53  
54 memory control task (Fig. 5F).

### 3.6 Behavioral correlations

Correlational analyses were used to address the hypothesis that specific diet-related changes in the microbiome were related to the behavioral changes. Analysis was limited to those orders of bacteria and behavioral measurements that showed significant differences between diet groups. There was a significant correlation between both cumulative proximity averaged across reversal trials (Fig. 6A; Table 3) and the average proximity to the old platform location in the reversal probe trial (Fig. 6B; Table 3) and the order of Firmacutes; Clostridia; Clostridiales. Higher percentages of the microbiome as Clostridiales were associated with poorer performance (higher cumulative proximities) in the reversal trials and searching closer to the old platform location (lower average proximities) in the reversal probe trial. Lower expression of Bacteroidales was also associated with a lower average proximity to the old platform location in the reversal probe trial (Fig. 6C; Table 3). Higher percentages of Lactobacillales showed a trend for poorer performance in the first probe trial (Fig. 6D; Table 3).

## 4. DISCUSSION

This study showed alterations in multiple orders and genera of bacteria in the feces of male mice after only 2 weeks on high-energy diets. Some similarities in alterations in the microbiome were seen when comparing the normal diet to both the high fat and high sucrose diets (e.g., Clostridiales), but the percentage decreases in Bacteroidales were greater in the high sucrose diet mice. In contrast, Lactobacillales was only significantly increased in the high sucrose diet group and Erysipelotrichales was only significantly affected by the high fat diet. The mice on the high sucrose diet had significant problems with cognitive flexibility, working memory, and development of a spatial bias early in training for long-term memory. Higher percentages of Clostridiales and lower percentages of Bacteroidales in the high fat and high sucrose diet groups were associated with poorer performance in the reversal trials for assessing cognitive flexibility.

1  
2  
3  
4 Many changes in the microbiome from the normal diet were found in both the high sucrose  
5 and high fat groups, but the animals on the high sucrose diet showed more significant  
6 alterations. There were no differences in bacterial expression between the assigned groups  
7 prior to the diet change, suggesting that the cage rotation was successful in normalizing the  
8 microbiota across subjects. Post-diet change, the order Bacteriodales, as well as members  
9 within its family Porphyromonadaceae, were significantly reduced in representation within the  
10 fecal microbiome in the high fat diet group, as compared to mice on the normal diet. The high  
11 sucrose group had even greater declines, having significantly lower expression than both the  
12 normal and high fat diet groups. Bacteriodales includes gram-negative, anaerobic, bacteria that  
13 are commonly found in the environment, gut and skin (Eckburg et al., 2005). Bacteria within the  
14 phylum Firmacutes tended to increase in prevalence in the high fat and/or the high sucrose diet  
15 groups. Bacteria within Firmacutes are gram-positives organisms and include the gut  
16 commensal Clostridia (Ludwig et al., 2009). Similar changes in Bacteriodales and Firmacutes  
17 have been reported in animals on Western diets and in obese mice with a leptin mutation (Ley  
18 et al., 2005, Turnbaugh et al., 2008, Turnbaugh et al., 2009, Ohland et al., 2013, Patterson et al.,  
19 2014) and in obese humans (Ley et al., 2006b), but see (Vrieze et al., 2012).

20  
21  
22  
23  
24  
25  
26  
27  
28  
29  
30  
31  
32  
33  
34  
35  
36  
37  
38  
39  
40 There was some variation in dietary effects on the orders within the Firmacutes phylum. The  
41 order Clostridiales and bacteria within its Lachnospiraceae and Ruminococcaceae families  
42 showed increased expression in both the high sucrose and high fat diet groups. Clostridiales  
43 bacteria are gram positive, obligate anaerobes. Lactobacillales and its genera Lactobacillus  
44 and Lactococcus were significantly increased, compared to normal, only in animals on the high  
45 sucrose diet. The genus Enterococcus was only expressed in the high sucrose diet group, but  
46 the percentage was less than .2%. Lactobacillales bacteria are gram-positive and Lactobacillus  
47 is commonly found in probiotics (Reid, 1999). Erysipelotrichales bacteria were only significantly  
48 increased from normal in the high fat diet mice. A similar increase in this order has been seen  
49 with humanized mice on a diet enriched in fat (Turnbaugh et al., 2009).

1  
2  
3  
4       Significant declines in performance in the water maze were confined to the mice on the high  
5  
6 sucrose diet. Four weeks after the diet change, mice on the high sucrose diet showed  
7  
8 impairment in retrieval of long-term memory in the probe trial on the first day of testing. There  
9  
10 was, however, no significant effect of diet overall on place trial learning for long-term memory.  
11  
12 This suggests that performance was similar across groups when the platform was present, but  
13  
14 the high sucrose diet animals had not developed a strong enough spatial bias on the first day to  
15  
16 retrieve the memory one hour after training (Gallagher et al., 1993). Long Evans rats that were  
17  
18 supplemented with sucrose showed impairment in the water maze throughout long-term  
19  
20 memory testing after 5 weeks on the supplemented diet (Jurdak et al., 2008), suggesting that  
21  
22 continued exposure to the diet may exacerbate memory deterioration. However, Sprague-  
23  
24 Dawley rats on a high-energy diet showed spatial long- and short-term memory problems in a  
25  
26 radial maze task after only 72 hours, and maintained these behavioral changes up to 90 days  
27  
28 (Kanoski and Davidson, 2010). Non-spatial long- and short-term memory deficits also emerged,  
29  
30 but only after 30 days (Kanoski and Davidson, 2010). The relatively small effect of diet on long-  
31  
32 term memory in the present study could be due to species and/or task differences. The mice on  
33  
34 the high sucrose diet in this study did, however, show significant deficits in spatial short-term  
35  
36 memory, similar to the rats (Kanoski and Davidson, 2010).  
37  
38  
39  
40

41  
42       Several types of Lactobacillales, including Enterococcus, Lactococcus and Lactobacillus,  
43  
44 increased in prevalence in the high sucrose diet group, which also had the greatest deficits in  
45  
46 early development of a spatial bias and in spatial short-term memory. There was also a trend for  
47  
48 animals with higher percentages of Lactobacillales to be more impaired in developing a spatial  
49  
50 bias early in training. Interestingly, Lactobacillus is often included in probiotic treatments (Reid,  
51  
52 1999), which have been shown to reduce stress-induced memory problems; altering short-term  
53  
54 memory impairments and N-methyl-D-aspartate (NMDA) receptor and BDNF changes  
55  
56 associated with stress (Collins et al., 2012). Lactobacillus- and bifidobacterium-containing  
57  
58 probiotics enhance place learning in the water maze in diabetic and control rats and memory  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 and long-term potentiation in diabetic rats (Davari et al., 2013). It is possible that the increases  
5  
6 seen in *Lactobacillus* in this study were too small to counteract the negative effects of other  
7  
8 bacterial or dietary changes, or that the high sucrose diet enhanced the prevalence of non-  
9  
10 beneficial species of *Lactobacillales*. No significant relationships were found between any of the  
11  
12 altered bacterial orders and short-term memory performance in this study.  
13  
14

15 The high sucrose group showed continued improvement in long-term memory, even  
16  
17 showing a trend for improved performance over the normal diet mice by Day 4, indicating that  
18  
19 the mice were able to develop a spatial bias with increased repetition. However, the mice on  
20  
21 the high sucrose diet were then impaired in learning a new platform location, which suggests the  
22  
23 mice had deficits in cognitive flexibility. There was not a significant difference between diet  
24  
25 groups in proximity to the new platform location during the probe trial after one day of reversal  
26  
27 training, but both the high fat- and high sucrose-fed mice spent more time during that probe trial  
28  
29 near the old platform location than the chow-fed mice. Rats on high fat diets rich in dextrose  
30  
31 show impairments in discrimination reversal learning, which is related to reductions in BDNF in  
32  
33 both the prefrontal cortex and hippocampus (Kanoski et al., 2007). Whether the performances in  
34  
35 the reversal training and probe trials was due to enhanced hippocampal learning following  
36  
37 extended training or problems with perseveration, involving the prefrontal cortex (Moffat et al.,  
38  
39 2007), remains to be determined.  
40  
41  
42  
43

44 Both *Bacteroidales* and *Clostridiales* showed progressive changes across diets and  
45  
46 relationships to reduced cognitive flexibility. Increased *Clostridiales* in the high-energy diet  
47  
48 groups was related to impaired performance in reversal trials with the platform present and an  
49  
50 increased search near the old platform position in the reversal probe trial. Lower percentages of  
51  
52 *Bacteroidales* were also related to searching more for the old platform position than the normal  
53  
54 animals.  
55  
56

57 Both *Clostridiales* and *Bacteroidales* have been associated with autism. In a study looking at  
58  
59 autism and Pervasive Developmental Disorder Not Otherwise Specified (PDD-NOS), the most  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 commonly recruited population in afflicted individuals was Clostridiales; Ruminococcaceae (De  
5 Angelis et al., 2013), which was also increased in expression in both of the high energy diet  
6  
7 groups in the present study. Treatment with *Bacteroides fragillis* improves gut permeability and  
8  
9 decreases autism spectrum disorders in the maternal immune activation mouse model (Hsiao et  
10 al., 2013). Prenatal exposure to valproic acid, another mouse model of autism spectrum  
11  
12 disorders, causes increases in Clostridiales and decreases in Bacteroidales, similar to high-  
13  
14 energy diets. These animals have deficits in social and repetitive behaviors (de Theije et al.,  
15  
16 2014), which involve prefrontal cortex (Mundy, 2003, Lopez et al., 2005). These repetitive  
17  
18 behaviors are influenced by alterations in working memory and response inhibition (Lopez et al.,  
19  
20 2005). Most of the microbiota/brain interaction studies show changes in BDNF expression or  
21  
22 electrophysiology in the hippocampus and/or amygdala (Bercik et al., 2011, Gareau et al., 2011,  
23  
24 Neufeld et al., 2011, Collins et al., 2012, Davari et al., 2013). However, there is evidence of  
25  
26 changes in GABA receptors in the prefrontal cortex with *Lactobacillus rhamnosus* treatment  
27  
28 (Bravo et al., 2011). These studies support a relationship between alterations in Clostridiales  
29  
30 and Bacteroidales and perseveration in the reversal trials. However, in individuals with cirrhosis  
31  
32 of the liver and hepatic encephalopathy, higher expression of members of the Clostridiales,  
33  
34 including Lachnospiraceae and Ruminococcaceae families, and lower expression of  
35  
36 Bacteroidales; Porphyromonadaceae and Rikenellaceae were associated with good cognition  
37  
38 (Bajaj, 2014). It seems likely that Clostridiales and Bacteroidales interact with the status of other  
39  
40 systems in the body to influence higher brain function.  
41  
42  
43  
44  
45  
46  
47

48  
49 Mice on the high fat diet did not significantly differ from the chow-fed mice in behavioral  
50  
51 testing, except for remaining focused on the old platform position during the reversal probe trial.  
52  
53 Rats on high fat diets for 90 days are impaired in reversal discrimination learning, working  
54  
55 memory and rules learning (Greenwood and Winocur, 1990, Kanoski et al., 2007). Sprague-  
56  
57 Dawley rats that became obese on a high fat diet showed impaired hippocampal function and  
58  
59 breached blood brain barrier (Davidson et al., 2012). The high fat diet mice in this study showed  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 enhanced weight gain as compared to both other groups across all weeks, but only exhibited  
5 greater body weight than the group on the high sucrose diet on the last weighing. Long Evans  
6 rats that were supplemented with Crisco showed impairment in the water maze on day 1 of  
7 testing after 5 weeks (Jurdak et al., 2008). Mice fed 45% fat for 12 months, however, showed no  
8 significant deficits in the water maze at 5 and 10 months (Mielke et al., 2006). Interestingly, mice  
9 fed 33% fat, in the form of lean ground beef, showed better long- and short-term memory than  
10 those on 12% fat (Li et al., 2009).

11  
12  
13  
14  
15  
16  
17  
18  
19  
20 There was no effect of diet on step-down latency or time in the center of the open field,  
21 indicating that the diets did not significantly affect anxiety. The lack of differences in speed of  
22 movement and distance traveled in the open arena and/or water maze suggest that the water  
23 maze results were not likely to be due to mobility differences. There were no effects of the diets  
24 on novel object or location recognition in this study, although Long-Evans rats fed sucrose for a  
25 longer duration (8 weeks) were impaired in the 1 hour retention test (Jurdak and Kanarek, 2009).

## 5. CONCLUSION

This study showed that both high-energy diets caused shifts in the composition of the microbiome, but more bacterial orders and genera were altered by the high sucrose diet than the high fat group. The high sucrose diets also interfered with early development of a spatial bias, cognitive flexibility and working memory to a greater degree than high fat diets. A diet-induced increase in bacteria from the order Clostridiales and a decrease in Bacteroidales were both associated with poor cognitive flexibility. These results suggest that specific bacterial orders within the microbiota may contribute to the effects of Western diets on cognitive function.

## FIGURE LEGENDS

**Fig. 1.** Effects of diet on body weight (A), change in body weight (B) and average consumption per day (C). Mice on the high fat diet had a significantly higher body weight in week 5 than the high sucrose-fed animals (#; A) and greater increases in body weight across the weeks, from the weight before the diet change, than both the normal and high sucrose diet groups (#; B). C) The mice in the normal diet group consumed more per day than either the high fat- or high sucrose-fed animals across all weighings (\*). Means  $\pm$  SEM. N = 6.  $p < .05$  for difference from high fat diet (#) or normal diet (\*) groups (ANOVA & Tukey's post-hoc test).

**Fig. 2.** Effects of diet on the percentages of bacterial classes in the fecal microbiome pre- and post-diet change in individual animals. Numbers on the x-axis indicate cage numbers of siblings housed together prior to the diet change. The A animals remained on normal diet. The B & C animals were changed from normal to high fat or high sucrose diets, respectively. N = 6. Means and SEM detailed in Table 2.

**Fig. 3.** There were no effects of diet on step-down latency (A), time spent in the center of an open field (B), distance traveled (C) and speed of exploration (D) in an open field; and percent exploration of novel objects (E,F) and objects in novel locations (G,H) after a one hour (E,G) and 24 hour (F,H) delay. On average across diet groups, animals stepped down more quickly (A) and spent more time in the center of an open field (B) post-diet change, as compared to pre-diet change (§), and animals explored the novel object above chance after a 1 hour delay post-diet change (\*; E) and after a 24 hour delay both pre- and post-diet change (\*; F). Means  $\pm$  SEM. N = 6. § indicates  $p < .05$  for difference between testing pre- versus post-diet change (ANOVA & Fisher's PLSD post-hoc test). \* indicates  $p < .05$  for difference from a chance level of 20% exploration time within a session (one-sample t-test).

1  
2  
3  
4 **Fig. 4.** Effects of diet on water maze performance for long-term memory (A,B) and cognitive  
5 flexibility (C,D). The mice on a high sucrose diet had higher proximity scores (searched more  
6 away from the platform) during probe trial 1 for long-term memory (B) and in reversal trials (C).  
7  
8 Both the high sucrose and high fat groups searched closer to the old platform location in the  
9 reversal probe trial than the mice on normal diet (D). Means  $\pm$  SEM. N = 6. \* indicates  $p < .05$   
10 for difference from the normal diet group (ANOVA & Fisher's PLSD post-hoc test).

20 **Fig. 5.** Effects of diet on delayed short-term memory (A-E) and a control task of associative  
21 memory (F). A-D) Naive and 10 minute delay trials for animals on normal (A), high fat (B), and  
22 high sucrose (C) diets for each session and averaged across sessions (D). E) The high  
23 sucrose-fed mice had significantly less difference between the naive and delayed short-term  
24 memory trials than the normal diet group. F) There was no effect of diet on the associative  
25 memory task. Means  $\pm$  SEM. N = 6. \* indicates  $p < .05$  for difference from the normal diet group  
26 (ANOVA & Fisher's PLSD post-hoc test).

38 **Fig. 6.** Correlations between bacterial orders and cognitive functions among individuals across  
39 diets. A,B) Higher percentages of Clostridiales in the microbiome were associated with poorer  
40 performance (higher proximity scores) for learning the new platform location in reversal trials (A)  
41 and with searching closer to the old platform location (lower proximity scores) in the reversal  
42 probe trial (B). C) Lower expressions of Bacteriodales were also associated with lower proximity  
43 scores for the old platform location. D) Higher percentages of Lactobacillales showed a trend for  
44 poorer performance in the first probe trial. Low proximity scores indicate a search pattern near  
45 the platform location. High proximity scores indicate that more of the search was spent away  
46 from the platform location. Significance level set to  $p < .01$ . N = 6.

\*\*\* indicates  $p < .001$  and \*\*\*\* indicates  $p < .0001$  for difference from normal diet group.

^ indicates  $p < .05$  and ^^ indicates  $p < .0001$  for difference from high fat diet group.

Two-way ANOVA, followed by Tukey's post-hoc analysis with correction for multiple comparisons with one family for all comparisons.

Bolded Orders are also shown in Fig. 5 and bold numbers represent sums of the unbolded subtaxa (averaged for each diet group) listed below on the table.

Only orders and genera expressed at  $> .01\%$  in at least one diet group were included in the analysis. The remaining taxa were summed and expressed as a percentage of the total remaining taxa.

Table 3. Pearson's correlation coefficients for relationships between bacterial orders and behavior in the water maze that exhibited significant differences between diets.

Bacterial orders	Long-term memory - probe trial 1 proximity	Reversal learning - averaged trials	Reversal probe - old location proximity	Short-term memory - trial differences
Bacteriodales	- .47	- .51	+ .60 **	+ .39
Lactobacillales	+ .50	+ .26	- .09	- .18
Clostridiales	+ .37	+ .60 **	- .73 **	- .44
Erysipelotrichales	+ .34	+ .002	- .28	- .17

\*\* indicates  $p < .01$  for a significant correlation.
