23 **ABSTRACT**

24 Soils in household environments in low- and middle-income countries may play an important
25 role in the persistence, proliferation, and transmission of *Escherichia coli*. Our goal was to
26 investigate the risk factors for detection, survival, and growth of *E. coli* in soils collected from
27 household plots. *E. coli* was enumerated in soil and fecal samples from human, chicken, and
28 cattle from 52 households in rural Bangladesh. Associations between *E. coli* concentrations in
29 soil, household-level factors, and soil physicochemical characteristics were investigated.
30 Susceptibility to 16 antibiotics and the presence of intestinal pathotypes were evaluated for 175
31 *E. coli* isolates. The growth and survival of *E. coli* in microcosms using soil collected from the
32 households were also assessed. *E. coli* was isolated from 44.2% of the soil samples with an
33 average of 1.95 log₁₀ CFU/g dry soil. Soil moisture and clay content were associated with *E. coli*
34 concentration in soil, whereas no household factor was significantly correlated. Antibiotic
35 resistance and pathogenicity were common among *E. coli* isolates, with 42.3% resistant to at
36 least one antibiotic, 12.6% multidrug-resistant (≥ 3 classes), and 10% potentially pathogenic. Soil
37 microcosms demonstrate growth and/or survival of *E. coli*, including an enteropathogenic,
38 ESBL-producing isolate, in some, but not all, of the household soils tested. In rural Bangladesh,
39 defined soil physicochemical characteristics appear more influential for *E. coli* detection in soils
40 than household-level risk factors. Soils may act as reservoirs in the transmission of antibiotic-
41 resistant and potentially pathogenic *E. coli*, and therefore may impact effectiveness of water,
42 sanitation, and hygiene interventions.

43 **IMPORTANCE**

44 Soil may represent a direct source or act as intermediary for transmission of antibiotic-resistant
45 and pathogenic *Escherichia coli*, particularly in low-income and rural settings. Thus, determining
46 risk factors associated with detection, growth, and long term survival of *E. coli* in soil
47 environments is important for public health. Here we demonstrated that household soils in rural
48 Bangladesh are reservoirs for antibiotic-resistant and potentially pathogenic *E. coli*, can support
49 *E. coli* growth and survival, and defined soil physicochemical characteristics are drivers of *E.*
50 *coli* survival in this environment. In contrast, we found no evidence that household-level factors,
51 including water, sanitation, and hygiene indicators, were associated with *E. coli* contamination of
52 household soils.

53 **INTRODUCTION**

54 The relative importance of different routes of enteric disease transmission is not well understood
55 (1), even for the model organism, traditional indicator of fecal contamination, and frequent
56 pathogen *Escherichia coli* (2). *E. coli* transmission is traditionally considered to occur via the
57 fecal-oral route (2) or through interactions with environmental compartments contaminated with
58 feces (i.e., water, hands and soils) (3, 4). Interactions of infected, colonized, and susceptible
59 hosts (human and animal) with environmental compartments plays an important role in enteric
60 disease transmission, and *E. coli* specifically (3). *E. coli* pathotypes infect multiple host species
61 (i.e., humans, ruminants, and chickens) that are often in close contact and share space, especially
62 in low and middle income countries (LMICs) (1). Understanding transmission of *E. coli*
63 pathotypes is important in developing effective water, sanitation, and hygiene (WASH)
64 interventions (3).

65
66 Research and WASH interventions have primarily focused on improving microbial quality in
67 water and food. Recent evidence suggests that other reservoirs (i.e., hands, soil), also act as
68 intermediaries of transmission either directly (i.e., hand-to-mouth contacts, soil ingestion) or
69 indirectly (through interactions with other environmental matrices) (5–9). Effective interventions
70 may need to limit transmission through microbial control of these additional reservoirs. Indeed,
71 of three recent randomized controlled trials of WASH investments in Bangladesh, Kenya (the
72 WASH Benefits Trials), and Zimbabwe (the SHINE trial), only the WASH Benefits Trial in
73 Bangladesh showed reductions in child diarrheal disease (10–13). The failure of WASH
74 investments on improvement of health may be partially attributed to the failure of the

75 interventions to adequately reduce enteric pathogens and fecal contamination in environmental
76 compartments, including soils (14).

77

78 Pathogen transmission via soil is particularly relevant for children given the high rates of
79 observed soil ingestion in LMICs (5, 6, 15). For example, one study in rural Zimbabwe estimated
80 that a one year-old child may ingest more than 20 g of soil per day as a result of both active soil
81 ingestion and mouthing episodes with soil contaminated hands (8). Furthermore, the soil in
82 households in LMICs is frequently found to contain high concentrations of *E. coli* (6, 16, 17).
83 The detected *E. coli* include multiple intestinal pathotypes, as evidenced by a study in Tanzania
84 (17), indicating that soils may be contributing to pathogenic *E. coli* transmission in these
85 settings. Similarly, soil may play a role in transmission of antibiotic-resistant *E. coli*, which have
86 also been detected in soils (18). Consumption of fresh produce grown in soils contaminated with
87 *E. coli* also represent a health risk (19), as it has been shown that even after washing
88 concentration of bacteria can remain high (20).

89

90 The high concentrations of *E. coli* in soil may be linked to soil-associated growth and/or
91 survival. Growth dynamics of *E. coli* have been studied in soils, sand, and sediments to
92 demonstrate potential limitations of *E. coli* as an indicator of fecal contamination (21–23). For
93 example, Ishii et al. hypothesized that *E. coli* are naturalized to the soil environment as stable
94 members of the soil microflora based on isolation of the same *E. coli* genotypes at the same
95 location repeatedly over one year (21). In addition, the phylogenomic analysis of five
96 *Escherichia* clades (isolated primarily from environmental compartments), which are
97 phenotypically indistinguishable but genetically distinct from *E. coli* (24, 25), has strengthened

98 the view that there are environmentally-adapted lineages. This was previously suggested by
99 Byappanahalli et al. after observing distinct DNA fingerprints of *E. coli* strains from soils as
100 compared to strains from animal sources (26). The existence of environmentally-adapted
101 lineages suggests the possibility of strain-specific adaptation for survival and/or growth in soil.
102 However, it is also clear that survival and/or growth is influenced by environmental factors
103 including temperature, water content, nutrient availability, soil texture, pH, solar radiation, and
104 the presence of soil indigenous microflora (27–31).

105

106 In recent years, more attention has been given to the role that environmental matrices play in
107 pathogenic *E. coli* transmission. However, fundamental questions remain about the importance
108 of *E. coli* adaptability, survival and growth in the environment. In this study we evaluate *E. coli*
109 ecology in soils collected from Mirzapur, Bangladesh, with the focus of soil as a reservoir for *E.*
110 *coli* transmission. Specifically, we investigated risk factors associated with the detection and
111 concentration of *E. coli* in household soils in rural Bangladesh. We also assessed survival and
112 growth dynamics of antibiotic-resistant and potentially pathogenic *E. coli* in soil microcosms to
113 further highlight mechanisms by which soil intrinsic properties influence *E. coli* detection,
114 survival, and/or growth.

115 **RESULTS AND DISCUSSION**

116 **Household characteristics, animal ownership, and feces management**

117 Survey data on household characteristics, including animal ownership and feces management,
118 allowed comparison of the study site to previous studies, and provided insight into the
119 importance of household-level factors that may contribute to increased *E. coli* in the soil. We
120 found enrolled households were generally more affluent, with respect to durable assets and
121 animal ownership, than typical rural households in Bangladesh, as described by the 2014
122 Demographic Health Survey (32) (Table 1, Table S1). For example, households reported higher
123 ownership of electricity, televisions, mobile phones, refrigerators, wardrobes, fans, cows/bulls,
124 and chickens/ducks (Table S1). To assign households to wealth quartiles based on durable assets,
125 animal ownership, and household characteristics, composite wealth indices were constructed
126 using principal components analysis. Indices ranged from -0.39 to 4.52, and correlated
127 moderately with self-reported monthly expenditures (Spearman's $\rho = 0.53$, $p < 0.001$). Wealth
128 quartiles were defined using k-means clustering, with 33%, 21%, 29%, and 17% of households
129 categorized in the poorest, second, third, and wealthiest quartiles, respectively (Table 1). Wealth
130 quartiles represent variation in wealth only among households enrolled in study.

131

132 Among enrolled households, sanitation was generally improved relative to the status reported in
133 the 2014 Demographic Health Survey for rural Bangladesh (32). For example, 71.2% of
134 households in this study had improved latrines with basic sanitation services as compared to
135 43.6% in rural Bangladesh (Table 1, Table S1). Nevertheless, visible feces were observed in
136 57.7% of the toilets/latrines, while only 11.5% had soap. Toilet/latrines were shared among 1 to
137 5 people in 51.9% of the households while 48.1% were shared among 6 to 19 people (Table 1).

138 Among the 18 households with children under five years (Table 1), 55.6% reported the child
139 uses the toilet and none reported the use of diapers. The most common way (44.4%) to manage
140 the child feces was disposal into the garbage. All the households had domestic animals (Table 1,
141 Table S1) and all reported that the animals defecate on the ground inside the household plot.
142 Diarrhea (defined as 3 or more episodes of loose/watery stool per day) or respiratory symptoms
143 (runny nose and cough) seven days prior to the interview date was reported in at least one
144 member of the household in 11.5% and 67.3% of the instances, respectively (Table 1).

145

146 ***E. coli* concentrations in household soils**

147 Presumptive *E. coli* was isolated from 44.2% (n=23/52) of the soil samples collected in the
148 household plots with an average \pm standard deviation of $1.95 \pm 0.88 \log_{10}$ *E. coli* CFU/g dry soil
149 and a maximum count of $3.86 \log_{10}$ *E. coli* CFU/g dry soil. The mean and maximum *E. coli*
150 concentrations observed in this study were similar to other studies in Tanzania and Zimbabwe
151 (17, 33), but lower compared to a previous study in rural Bangladesh (16). Species identification
152 using the API-20E system confirmed *E. coli* in the 23 soil samples (100%). The majority of
153 isolates (21/23) were identified with a confidence level > 95%, while only 2/23 showed lower
154 discrimination confidence. The API-20E results also indicated high phenotypic diversity among
155 the isolates, as indicated by 10 unique biochemical profiles. Random amplified polymorphic
156 DNA (RAPD) confirmed high degree of genetic diversity among the soil isolates. All isolates
157 showed unique fingerprint patterns and only nine isolates clustered together in three RAPD types
158 with similarity greater than 80% (RAPD types G, I, and K; Fig. S1). PCR detection of the *E. coli*
159 gene *uidA* from DNA extracted directly from the soil samples increased, albeit not substantially,
160 *E. coli* detection from 44.2% to 57.7 % (n=30/52). This result indicates that the culture method

161 used for isolation was able to recover *E. coli* in the majority of soil samples where *E. coli* DNA
162 was detected.

163

164 **Associations between soil characteristics and *E. coli* concentrations in soil**

165 We evaluated *E. coli* concentration associations with different soil characteristics measured as
166 these varied across households. Soil water content was significantly correlated with the
167 concentration of *E. coli* in soils (Spearman's $\rho = 0.48$, $p = 0.0003$; Table S2), consistent with
168 previous studies (16, 28, 33). Water content in the 52 soil samples varied between 9.8% and
169 38.4% with a mean \pm standard deviation of $20.8 \pm 7\%$ (Table S2). The only other soil
170 physicochemical parameter that was found associated with *E. coli* concentrations was the
171 percentage of clay, with an inverse correlation (Spearman's $\rho = -0.47$, $p = 0.0095$; Table S2).
172 The mechanism explaining the inverse relationship between *E. coli* concentration and clay is
173 unclear. In agreement with our findings, Lang et al. reported higher background concentration of
174 *E. coli* in a sandy loam soil (73% sand, 19% silt, and 8% clay) than in a silty clay soil (11% sand,
175 53% silt, and 36% clay) (34). In contrast, previous studies have observed a higher proportion of
176 bacteria (35) and preferential attachment (36) in the clay fraction of soil compared to the other
177 fractions. *E. coli* O157 was also observed to survive longer in loam and clay soils compared to a
178 sandy soil (37). In addition, Brennan et al. showed that the addition of different clay minerals
179 (clay mineral composition varies among soils) influenced other physicochemical soil properties
180 and differentially affected survival of enteropathogens (38). The contrasting results may also be
181 due to differences in the methods for bacterial recovery, suggesting further evaluation of the
182 methodology for *E. coli* enumeration in soils may be warranted. Correlations with other soil

183 properties (field capacity; permanganate oxidizable active organic carbon; active organic carbon;
184 total nitrogen; percentage of clay, silt, and sand in soil) were not significant (Table S2).

185

186 **Associations between household characteristics and *E. coli* concentrations in soil**

187 Differences in household characteristics, WASH indicators, diarrhea/respiratory symptoms, and
188 animal ownership could not account for differences in *E. coli* concentration in soils (Table 1).

189 This study was designed to include the same number of households with ruminants and without
190 ruminants in order to determine if ruminants significantly increase *E. coli* contamination in the

191 household soil environment. Our results indicate that the presence of ruminants in the vicinity of
192 the household plot was not associated with *E. coli* concentration (Wilcoxon $p = 0.31$) (Table 1)

193 or presence/absence of culturable *E. coli* in soils (Fisher's exact $p = 0.58$). In previous studies,
194 the presence of roaming animals and animals in general has been associated with higher level of

195 *E. coli* in soils, although the difference in concentration was low (0.22 and 0.54 \log_{10} CFU/g dry
196 soil, respectively) (16, 33). Our study was likely underpowered to observe significance between

197 WASH indicators and concentration of *E. coli* in soils at the previously observed effect size. For
198 example, all the households included in our study had chickens and other domestic animals that

199 defecate inside the household plot and could potentially contribute to contamination of soils by
200 *E. coli*. Indeed, not only a ruminant-associated molecular source tracking (MST) marker (BacR)

201 but also an avian-associated MST marker (avian-GFD) have been detected in soil samples in
202 rural Bangladeshi households (39). Nevertheless, the absence of a clear relationship between *E.*

203 *coli* contamination in soils and household-level factors stands in contrast to the relationships

204 observed with soil properties (moisture content, clay percentage).

205 **Antibiotic resistance pattern and presence of extended-spectrum beta-lactamase (ESBL)**
206 **genes**

207 The level of susceptibility to a panel of 16 antibiotics was evaluated among the 175 *E. coli*
208 isolated from soil (n=23) and fecal samples from human (n=50), chicken (n=51), and cattle
209 (n=51). Overall, 42.3% of the isolates were resistant to at least one antibiotic category and 12.6%
210 were resistant to 3 or more antibiotic categories, thus classified as multidrug resistant (MDR)
211 (Table 2). Resistance to tetracycline (27.4%) and ampicillin (20.6%) were predominant, followed
212 by resistance to nalidixic acid (12.6%) and trimethoprim-sulfamethoxazole (10.3%). Resistance
213 to other antibiotics were less prevalent (1.1 - 5.7%), while no resistance to piperacillin-
214 tazobactam, meropenem, imipenem, and amikacin was observed (Table S3).

215

216 Resistance was more commonly observed in *E. coli* isolated from chickens (56.9%) and humans
217 (54.0%) than in *E. coli* from ruminants (15.7%). The proportion of *E. coli* isolates from soil
218 resistant to at least one antibiotic category (43.5 %) was closer to the proportional resistance
219 among *E. coli* from chicken and human isolates than in isolates from ruminants. Notably, 13.0%
220 of soil isolates were MDR (Table 2). The similarity in prevalence and resistance patterns
221 observed among *E. coli* isolates from soils, human feces, and chicken feces, aligns with prior
222 work identifying similar genotypic and phenotypic characteristics among isolates from soil,
223 human feces, and chicken feces (40). The data support the potential for human and/or chicken
224 feces to be a source of soil *E. coli*. Although antibiotic resistance data of *E. coli* from household
225 soils is scarce, as the majority of prior studies focused on resistance in agricultural soils, the
226 prevalence observed here is concerning, especially considering that we did not use antibiotic-
227 selective media for isolation. Whether the *E. coli* isolated are a result of direct fecal input or if

228 they represent environmental populations that are genetically different from the fecal sources is
229 currently unknown and represents an interesting research topic for further investigation.
230
231 Interestingly, resistance to third-generation cephalosporins was detected with a frequency
232 slightly higher in *E. coli* isolated from soils than in *E. coli* isolated from fecal sources (Table S3).
233 Third-generation cephalosporins are an important family of antibiotics widely used for treatment
234 of infections with Gram-negative bacteria. Soils are regarded as selective environments due to
235 the presence of many antibiotic compounds produced by soil bacteria (41). Furthermore,
236 anthropogenic release of antibiotics and antibiotic derivatives into soils may contribute to the
237 proliferation of antibiotic-resistant bacteria (18). For example, most cephalosporins administered
238 parenterally to humans and animals, are eliminated rapidly through urine (42). Therefore,
239 selection of antibiotic-resistant bacteria not only occurs in the individual or animal taking the
240 antibiotic but may also occur in the environmental compartment receiving the residues (18).
241 Nonetheless, it is important to consider that soil resistomes are complex and antibiotic resistance
242 genes have been documented in high abundance in soils regardless of recent anthropogenic
243 influence (43, 44).
244
245 We found ten isolates resistant to third-generation cephalosporins, from which seven (two
246 isolated from soils) were confirmed as ESBL producers by the double-disk synergy test (DDST)
247 and carried the beta-lactamase gene *bla*_{CTX-M-group-1}. In addition, two isolates co-harbored another
248 ESBL gene (*bla*_{TEM} or *bla*_{OXA-1-like}). The presence of *E. coli* resistant to third-generation
249 cephalosporins (including ESBL producers) in domestic soils in Bangladesh, suggests that this
250 environmental compartment may play a role in child exposures to antimicrobial-resistant

251 bacteria. Children (3 to 18 months) in a similar setting were observed to frequently ingest soil
252 and mouth hands and objects after touching soil (8, 15). Exposure to ESBL-producing organisms
253 through soil contact is concerning, as septicemia caused by ESBL-producing organisms has an
254 elevated risk for fatality relative to septicemia caused by antibiotic susceptible infections (45).

255

256 **Distribution of intestinal pathotypes among *E. coli* from soil and fecal sources**

257 Overall 10.3% of the 175 *E. coli* isolates possessed at least one of ten intestinal virulence-
258 associated genes tested. Enteropathogenic *E. coli* (EPEC) was the most prevalent pathotype
259 encountered (4.6%) with seven of the eight EPEC isolates classified as atypical EPEC (only
260 carrying the *eae* gene) and the other as typical EPEC (carrying both *eae* and *bfp* genes). EPEC
261 was more frequently found in *E. coli* isolated from chickens feces (7.8%) than other sources, and
262 it was the only pathotype detected in chicken feces. In contrast, Shiga toxin-producing *E. coli*
263 (STEC) marked by the presence of *stx1* or *stx2*, was only detected in cattle feces. Of the 51 cattle
264 isolates tested, 11.8% were classified as STEC. Human fecal isolates showed higher diversity of
265 virulence-associated genes (*eae*, *bfp*, *aaiC* and *lt*), as three different pathotypes (EPEC,
266 enteroaggregative *E. coli* (EAEC), and enterotoxigenic *E. coli* (ETEC)) were detected in human
267 fecal isolates. From soil samples, one isolate was found to carry *aat* and *aaiC*, indicative of
268 EAEC, while another isolate carried *eae*, indicative of atypical EPEC (Table 3). Detection of *eae*
269 gene in DNA extracted directly from soils revealed presence of EPEC in an additional soil
270 sample. Enteroinvasive *E. coli* (EIEC) was not detected in any of the studied isolates (Table 3).

271

272 Notably, the proportion of potentially pathogenic *E. coli* reported in this study is not directly
273 comparable to other studies where enrichment for pathotypes or pooled DNA extraction followed

274 by molecular methods have been performed (17, 46). In our study *E. coli* was isolated in tryptone
275 bile x-glucuronide (TBX) agar, which is a selective agar for *E. coli* detection irrespective of
276 pathogenicity, thus the *E. coli* isolated in this media represent the total culturable *E. coli* present
277 in the samples. The presence of virulence genes in 8.7% of the randomly selected *E. coli*
278 colonies recovered from soil samples (one per sample) suggests that within this study site, a
279 surprisingly high proportion of *E. coli* in soil are potentially pathogenic.

280

281 **Survival and growth of EPEC in domestic soil microcosms**

282 Four EPEC isolates, including both antibiotic sensitive and resistant strains (Table S4), readily
283 grew in the autoclaved natural standard soil, a commercially available sandy loam soil described
284 further in the methods section. Specifically, substantial growth was observed from day 0 (seeded
285 at a concentration of $\sim 10^3$ CFU/g dry soil) to day 3, when all isolates were detected at
286 concentrations of 10^8 CFU/g dry soil (Fig. 1a). Beyond day 3, the concentration decreased, but
287 remained higher than the concentrations observed immediately after spiking (Fig. 1a). The
288 kinetics of growth and persistence were similar for all four isolates (Fig. 1a, Fig. S2a). In
289 contrast, in non-autoclaved soil, there was a sharp decrease in the concentration at day 7 post-
290 seeding (Fig. S2b). By day 14, all four isolates were no longer detectable. These results support
291 previous findings that soil microflora reduce survival of *E. coli* in soil environments (28, 29).
292 Soil microflora impacts *E. coli* survival and/or growth through competition for available
293 nutrients and/or direct antagonistic relationships, such as predation by protozoa (47–49).
294 Additionally, autoclaving the soil may promote *E. coli* growth through release of nutrients, as for
295 example ammonium-N (50). In addition, the availability of organic compounds is important for
296 *E. coli* growth in soil environments (23, 27). Interestingly, adapting the EPEC isolates in

297 autoclaved soil before facing non-autoclaved soil substantially extended the survival time (Fig.
298 S2c). The adaptation experiment here is analogous to *E. coli* entering the environment via feces.
299

300 We next followed the fate of the four EPEC isolates in three other soils collected from the
301 households (soils HH-15, HH-29, and HH-34; Table S5). While no significant growth or survival
302 differences were seen among the four isolates, we observed growth varied by soil source (Fig.
303 1b). While the concentrations of the isolates increased in one soil (soil HH-29), mirroring what
304 was observed in the natural standard soil, concentrations of all isolates fell below the detection
305 limit as early as day 3 post-seeding in the other two soils (soils HH-15 and HH-34) (Fig. 1b).
306 This striking differences in EPEC growth and survival among different soils collected from the
307 households led us to study more Bangladeshi soils. In total, we selected 10 soils, five of which
308 had detectable *E. coli* and five of which did not at the time of sampling in the households (Table
309 S5). Growth and survival kinetics of one *E. coli* strain (26-H: isolated from human feces,
310 classified as typical EPEC, resistant to third-generation cephalosporins, ESBL producer, and
311 carrier of the CTX-M beta-lactamase; Table S4) was observed in half of the soils (Fig. 2).
312 Specifically, in four of the five soils where *E. coli* was detected at the time of collection, isolate
313 26-H was able to persist for 14 days after spiking the non-autoclaved soil fraction. In the other
314 soil (soil HH-25), isolate 26-H did not grow or persist (Fig. 2). In contrast, in four of the five
315 soils with no previous *E. coli* detection, isolate 26-H was not detected after spiking the non-
316 autoclaved soil. One soil (soil HH-11) with no previous *E. coli* detection was permissive of *E.*
317 *coli* survival (Fig. 2). No obvious soil characteristic related to growth was identified. For
318 example, the pH values of the ten soils tested were very similar and close to neutral values

319 (Table S5). Furthermore, soil-derived supernatant did not directly inhibit *E. coli* growth on
320 laboratory media, suggesting no *E. coli* growth inhibitor is present in the soils (data not shown).
321
322 *E. coli* growth is dependent on soil moisture content, as observed in soil microcosms.
323 Specifically, *E. coli* 26-H rapidly decreased in number below the lower limit of detection in
324 autoclaved soil 2.2 with adjusted moisture content of 5% (field capacity ~ 44.8%) (Fig. S3). In
325 contrast, when the moisture content of soil 2.2 was adjusted to 10%, 15%, or 20%, the
326 concentration of the isolate increased by 5 orders of magnitude (from $\sim 10^3$ to $\sim 10^8$ CFU/g-dry)
327 within 7 days. The results align with the aforementioned observed correlation between soil
328 moisture content and *E. coli* concentrations. The results also align with prior work identifying
329 water content as a major driver of survival kinetics of bacteria in soils (27, 28, 51) especially at
330 growth permissive temperatures. Notably, small differences in soil moisture content may also
331 influence *E. coli* survival and/or growth, particularly in the presence of soil microflora, which
332 contributes to a more competitive environment. Quantification using culture-based methods may
333 also influence recovery, as they may be unable to recover stressed bacterial cells, as for example
334 cells that have entered the viable but non-culturable (VBNC) state, at low moisture content or
335 under other environmental stressors (52, 53).
336
337 Overall, the findings of our study indicate that soil physicochemical properties influence the
338 detectability, concentration, and growth potential of *E. coli* - including potentially pathogenic
339 and antibiotic-resistant variants - in households in rural Bangladesh. In contrast, WASH
340 indicators were not significantly associated with *E. coli* contamination of household soils in our
341 study site. These findings suggest studies investigating transmission of *E. coli* in household

342 environments should consider soil ecology as a moderating variable between household-level
343 risk factors and *E. coli* detection. Soils may act as reservoirs in *E. coli* transmission by enabling
344 growth of antibiotic-resistant and potentially pathogenic *E. coli* variants, as demonstrated by our
345 microcosm studies. Risks from *E. coli* growth in soil are high, given the observed high rates of
346 soil ingestion (both directly and indirectly) among children in Bangladesh and other LMICs. We
347 also found that strain-specific adaptations to growth in soil may not be compulsory for
348 persistence in soil, as no differences in growth and survival rates among the isolates were
349 observed. Moreover, the presence and demonstrated growth of pathogenic and antimicrobial
350 resistant *E. coli* in these household soils suggests that other pathogenic bacterial species with
351 ecology similar to *E. coli* may have the potential to persist and/or grow in soil and therefore also
352 pose a risk to human health.

353

354 Further studies are warranted to determine the importance of growth and persistence of *E. coli*
355 and other pathogens in situ to complement our microcosm evidence. Elucidating the origin and
356 fate of pathogenic bacteria in domestic soil environments is important in order for designing
357 effective measures to control transmission. For example, programs to promote upgrading soil
358 flooring in households may help to reduce pathogen transmission as shown by the 13% reduction
359 in diarrheal disease observed in Mexico's Piso Firme program (54).

360 **MATERIALS AND METHODS**361 *Ethics statement and study site*

362 This study was performed following an approved protocol by the ethics committees of the Swiss
363 Federal Institute of Technology Zurich (ETH Zurich, Switzerland) and the International Centre
364 for Diarrhoeal Disease Research, Bangladesh (icddr,b, Dhaka, Bangladesh). The study was
365 conducted in 52 households with dirt/soil flooring located in rural villages of Mirzapur upazilla
366 in Tangail district of Bangladesh (26 households with ruminants and 26 households without
367 ruminants) during February to April of 2016. Researchers/enumerators from icddr,b, conducted
368 household surveys, soil sampling, and fecal sampling. A questionnaire-based survey was
369 conducted on households assets and infrastructure, gastrointestinal/respiratory illness among
370 household members, and agricultural/livestock practices as well as spot-check observations for
371 WASH infrastructure. Based on household assets, infrastructure, and livestock ownership,
372 household wealth was indicated by constructing a composite wealth index using principal
373 component analysis and k-means clustering. Environmental and fecal sampling included the
374 collection of one soil sample, one human fecal sample, one chicken fecal sample, and one cattle
375 (ruminant) fecal sample (if present) from each participating household, as later described.

376

377 *Soil and fecal sample collection*

378 Soils (n = 52), from the front yard of the households with no visible feces, food or trash, were
379 collected. Approx. 150 g of soil were aseptically retrieved from an area of 60 cm² and < 2 cm
380 depth, and stored on ice in a sterile Fisherbrand® sample bag (Fisher Scientific, Pennsylvania,
381 USA). Human fecal samples were provided in a stool container by household members (18 to 64
382 years old). Fecal samples from chickens and cattle, with fresh and glossy appearance, preferably

383 right after observing the animal deposit the feces, were aseptically collected by the enumerator.
384 Samples were stored on ice and transported to the Enteric and Food Microbiology Laboratory at
385 icddr,b, where they were stored at 4°C and processed within 24 hours of collection.

386

387 *Soil physicochemical analyses*

388 Soil physicochemical analyses were performed at the Department of Soil, Water and
389 Environment of the University of Dhaka. For all the soil samples, soil dry gravimetric water
390 content (GWC) was determined by drying 1 g of soil at 100°C for 16 h or until mass remained
391 constant. Field capacity (55) and permanganate oxidizable active organic carbon (mg/kg) (56,
392 57) were also measured. In addition, for a subset of 30 soil samples, particle size (58), active
393 organic carbon (%C) with the Walkley-Black chromic acid wet oxidation method (59), and total
394 nitrogen (%N) by the Kjeldahl method (60) were determined. For 10 soils used for the
395 microcosm studies, soil pH was determined in a 0.01 M calcium chloride solution at 1:1
396 soil:solution ratio (61).

397

398 *E. coli enumeration and isolation*

399 *E. coli* enumeration and isolation from soil and fecal samples was performed as previously
400 described (33) with slight modifications. In brief, 5 ± 0.25 g of soil or 1 ± 0.25 g of feces were
401 diluted in a sterile Fisherbrand® blender bag (Fisher Scientific, Pennsylvania, USA) and mixed
402 by hand for 2 min in 30 ml of phosphate buffered saline (PBS). The mixture was let to settle for
403 15 ± 3 min to allow sedimentation of bigger particles and for reproducible ten-fold serial
404 dilutions. For enumeration of *E. coli* from soils, 1 ml of each dilution were inoculated onto
405 tryptone bile x-glucuronide (TBX) agar (Oxoid, Basingstoke, UK) by the pour plate technique.

406 The lower limit of detection (LOD) for the soil samples was 0.99 log₁₀ CFU/g of dry soil. For
407 isolation of *E. coli* from feces, 100 µl of each dilution were spread plated onto TBX agar. All
408 plates were incubated at 37°C for 18-24 h and one colony (for soil, human and chicken samples),
409 or two colonies (for cattle samples) were selected, based on blue-green color appearance on the
410 TBX media, for species confirmation using the API-20E system (bioMerieux, Marcy-L'Étoile,
411 France). The confirmed *E. coli* isolates were given a number corresponding to the household
412 where the sample was collected (1 to 52) follow by the sample type: "S" for soil, "H" for human
413 fecal, "CH" for chicken fecal and "C" for cattle fecal (i.e. 15-CH corresponds to the *E. coli*
414 isolate recovered from a chicken fecal sample collected from household 15). *E. coli* isolates were
415 stored at -80°C at icddr,b and sent to Eawag (Dübendorf, Switzerland) for further analyses.

416

417 *Random amplified polymorphic DNA (RAPD)*

418 RAPD fingerprinting was performed on *E. coli* isolated from soils, using primer "4" (5'-
419 AAGAGCCCGT-3') (discrimination index 0.983) and following a procedure described
420 previously (62). Results were analyzed with the software Bionumerics 4.5. Similarity was
421 determined using the Dice coefficient and clustering was performed by the unweighted pair
422 group method with arithmetic means (UPGMA). RAPD patterns with a Dice coefficient >80%
423 were considered as probably related and assigned to the same cluster or RAPD type.

424

425 *Molecular detection of E. coli in soils.*

426 Molecular detection targeting the conserved beta-glucuronidase gene *uidA* in DNA extracted
427 from soils was performed to establish whether or not the culture-based approach resulted in
428 false-negatives. For DNA isolation from soil, 0.25 g of soil were additionally collected from

429 each household and added to a cryovial containing 1 ml of LifeGuard soil preservation solution
430 (Qiagen, Hilden, Germany). Soil samples were stored at -20°C and processed before 30 days
431 after collection. DNA was extracted using the PowerSoil DNA isolation kit (MoBio, California,
432 US) following the manufacturer's instructions. Molecular detection of *E. coli* was performed by
433 PCR, using primers targeting the beta-glucuronidase gene *uidA* (*uidA*_For 5'-
434 GCGTCTGTTGACTGGCAGGTGGTGG-3' and *uidA*_Rev 5'-
435 GTTGCCCGCTTCGAAACCAATGCCT-3'), a gene commonly found in *E. coli* (63) Reaction
436 conditions were as follows: 95°C for 5 min, followed by 30 cycles of 95°C for 30 s, 63°C for 30
437 s and 72°C for 30 s, and a final extension at 72°C for 5 min. DNA extracted from the *E. coli*
438 strain ATCC 25922 was used as positive control, while DNAase free water was used as non-
439 template control.

441 *Antibiotic susceptibility testing*

442 Antibiotic susceptibility of the 175 isolated *E. coli* was determined against 16 different antibiotic
443 disks (Oxoid, Basingstoke, UK) by standard disk diffusion technique following the Clinical
444 Laboratory Standards Institute (CLSI) guidelines and interpretation standards (64). The
445 evaluated antibiotics included representatives of five different antibiotic categories: beta-lactams:
446 ampicillin (AMP) and mecillinam (MEC) (penicillins); piperacillin-tazobactam (TZP) (beta-
447 lactam-beta-lactams inhibitors); aztreonam (ATM) (monobactam); cefixime (CFM), ceftriaxone
448 (CRO), cefotaxime (CTX) and ceftazidime (CAZ) (third-generation cephalosporins); meropenem
449 (MEM) and imipenem (IPM) (carbapenems); aminoglycosides: amikacin (AMK); tetracyclines:
450 tetracycline (TET); phenicols: chloramphenicol (CAM); quinolones: nalidixic acid (NAL) and
451 ciprofloxacin (CIP); folate pathway: trimethoprim-sulfamethoxazole (SXT). Multidrug resistance

452 was defined as non-susceptibility to at least one antibiotic in 3 or more categories as defined by
453 Magiorakos et al. (65). Double-disk synergy test (DDST) was carried out on 10 *E. coli* isolates
454 suspected to be ESBL producers (based on their resistance to third generation cephalosporins).
455 The DDST was considered positive when expansion of the inhibition zone of CTX, CRO, and/or
456 ATM disks towards a disk with clavulanic acid located 20 mm away was observed, as indicated
457 in Jalier et al. (66) with some modifications (67).

458

459 *Detection of virulence-associated and extended-spectrum beta-lactamases-encoding genes by*
460 *PCR*

461 Previously described PCR methods (68) were used for the detection of ten virulence-associated
462 genes indicative of five different *E. coli* intestinal pathotypes in the 175 *E. coli* isolates:
463 enteroaggregative *E. coli* (EAEC): *aiiC* (secreted protein) and *aat* (antiaggregation protein
464 transporter gene); enteroinvasive *E. coli* (EIEC): *ial* (invasion associated locus) and *ipaH*
465 (invasion plasmid antigen H); enteropathogenic *E. coli* (EPEC): *eae* (intimin) and *bfp* (bundle
466 forming pilus); enterotoxigenic *E. coli* (ETEC): *lt* (heat labile enterotoxin) and *st* (heat stable
467 enterotoxin) and Shiga toxin-producing *E. coli* (STEC): *stx1* and *stx2* (shiga toxins). Detection of
468 *eae* was also directly performed on the DNA isolated from soils. In addition, detection of the
469 beta-lactamase genes *bla*_{TEM}, *bla*_{SHV}, *bla*_{OXA-1-like} and *bla*_{CTX-M}, was performed on all ESBL-
470 producing *E. coli* isolates by multiplex PCR with previously described primers (69). A bacterial
471 strain known to carry the gene targeted by each primer pair was used as positive control. *E. coli*
472 strain ATCC 25922 and water were used as negative and non-template controls, respectively.

473

474 *Soil microcosm studies*

475 Growth and survival in soil was evaluated for four EPEC isolates (15-CH, 24-H, 26-H, and 29-
476 CH), including one isolate sensitive to all antibiotics while the other three isolates showed
477 different resistance profiles (Table S4). Some experiments were conducted only with the EPEC
478 isolate 26-H (resistant to third-generation cephalosporins, ESBL producer, and carrier of the
479 CTX-M beta-lactamase). Experiments were performed with a natural standard soil (soil type No.
480 2.2) from LUFA Speyer Germany (<http://www.lufa-speyer.de/index.php>) and 13 soils collected
481 from the households. The natural standard soil No. 2.2 is a commercially available sandy loam
482 soil with known physicochemical properties (Table S5), has not received pesticides, biocidal
483 fertilizers, or organic manure for at least 5 years, and so was used here as a control soil. Soils
484 were sieved through a 2.36 mm mesh followed by sterilization by 3 consecutive rounds of
485 autoclaving. Soil GWC was determined with 0.5 g of soil following the procedure mentioned
486 earlier. Before starting the experiments the soil GWC was adjusted to $15\% \pm 1\%$ GWC with
487 sterile double distilled water (ddH₂O). For one experiment the soil GWC was adjusted only at the
488 start of the experiment (Fig. 1) while for the others (Fig. 2, Fig. S2, and Fig. S3) the GWC was
489 adjusted if necessary after each time point measured. As autoclaving the soil impacts the
490 indigenous soil microbiota and likely affect some physicochemical soil properties (70, 71), we
491 compared the survival dynamics of the four EPEC isolates in autoclaved vs. non-autoclaved
492 standard soil. To find a scenario that likely resemble a more realistic condition that *E. coli*
493 encounters in domestic soil, a mix of sterilized and unsterilized soil in a ratio of 1:19 or 1:1 was
494 used. In this case, the sterile autoclaved soil fraction was seeded with *E. coli* and incubated for
495 seven days before spiking the non-autoclaved soil fraction with the seeded autoclaved soil. The
496 GWC adjusted soils (4-5 g) were placed into 50 ml tubes and maintained at room temperature

497 until used. Triplicate soil samples were prepared for each condition and for each *E. coli* isolate
498 evaluated. For inoculation into the soils, *E. coli* cells were prepared as previously described with
499 modifications (72). In brief, each *E. coli* isolate from overnight cultures in LB broth were diluted
500 into the same medium in triplicates to a starting OD₆₀₀ of 0.05 and grown to mid-logarithmic
501 phase (OD₆₀₀=0.6) at 37°C and 220 rpm. Cells were harvested at 6500 g for 5 min, washed twice
502 with 1X PBS to avoid media carry over and resuspended in 1X PBS to an estimated 10⁸ CFU/ml.
503 The cell suspension was diluted and soils were inoculated to a concentration of 10¹ - 10⁴ CFU/g
504 of dry soil. As non-inoculated and water content controls, sterile ddH₂O was added instead of the
505 bacterial suspension. Soil-bacteria microcosms were mixed by inversion for 1 min, followed by
506 vortex at maximum speed for 1 min. Right after mixing (day 0) the CFU/g of dry soil were
507 measured by withdrawing and suspending approx. 0.5 g of the inoculated soil (exact weights
508 were recorded for each sample) into 1X PBS, followed by 1 min vortex at maximum speed and
509 centrifugation at low speed (200 g for 2 min) to sediment soil particles. The resulting supernatant
510 was subjected to ten-fold serial dilutions and 25 µl volume from each dilution was drop-plated in
511 duplicates in TBX agar (73). The number of CFU was counted after overnight incubation at
512 37°C. The microcosms were incubated at 30°C, which is within the range of average temperature
513 in the study area. Furthermore, Islam et al., reported significant linearity between atmospheric
514 temperature and soil temperature at 5 cm depth in Bangladesh (74). Bacterial counts were
515 determined at different time points over a period of up to 84 days, as described for day 0. The
516 lower LOD for each microcosm experiment is indicated in the corresponding graphs.

517 *Inhibition assay*

518 Inhibitory effect of soil on growth of *E. coli* was investigated with six Bangladeshi soils, three
519 that were positive for *E. coli* isolation (HH-25, HH-46, HH-50) and three negative for *E. coli*
520 isolation (HH-04, HH-09, HH-10). For this, a 1:1 soil:PBS solution was prepared, vortexed at
521 maximum speed for 1 min and centrifuged at 200 g for 2 min. Ten μ l of the supernatant from
522 each soil:PBS solution were applied to the center of a Mueller Hinton agar plate previously
523 inoculated with the *E. coli* strain ATCC 25922. Zones of inhibition were measured after
524 overnight incubation at 37°C.

525

526 *Statistical analyses*

527 Data was analyzed using GraphPad Prism, version 7.0a (GraphPad Software, Inc. La Jolla, CA)
528 and R version 3.4.3. All concentrations are expressed as \log_{10} *E. coli* CFU per gram of dry soil,
529 as the soil GWC was determined. When the CFU counts were below the lower LOD, half the
530 lower LOD was assumed for all subsequent quantitative analyses. Wilcoxon signed rank test and
531 Kruskal-Wallis test by ranks were used to compare mean ranks of *E. coli* concentration in soil
532 among groups obtained from the survey data. To evaluate if the presence of ruminants is
533 associated with presence and concentration of *E. coli* in soils, Fisher's exact and Wilcoxon
534 signed rank test were used, respectively. Association between \log_{10} *E. coli* CFU/g of dry soil and
535 monthly expenditures, toilet age, or the soil physicochemical parameters was evaluated using
536 Spearman's rank correlation analysis. Differences in the proportion of resistant isolates among
537 sources were evaluated using Fisher's exact. For the soil microcosm results, significant
538 differences in the geometric mean of \log_{10} *E. coli* CFU/g of dry soil were evaluated using one-

539 way ANOVA with post-hoc analysis (Tukey's multiple comparisons test) or independent

540 Student's *t*-test.

766 **Table 1.** Characteristics of the 52 households in Mirzapur, Bangladesh enrolled in this study
767 along with *E. coli* counts in soil.

Characteristics	n	Percent (%)	<i>E. coli</i> log ₁₀ CFU/g-dry soil		Sig.	Test
			Mean	SD		
Wealth Quartile					p = 0.96	<i>Kruskal-Wallis test by ranks</i>
First (Poorest)	17	33	1.27	0.80		
Second	11	21	1.25	1.05		
Third	15	29	1.11	0.69		
Fourth (Wealthiest)	9	17	1.41	1.08		
Monthly Expenditures					p = 0.86	<i>Spearman's rank correlation (ρ = -0.03)</i>
Toilet/Latrine					p = 0.29	<i>Kruskal-Wallis test by ranks</i>
Improved - Basic	37	71.2	1.14	0.79		
Improved - Limited	13	25	1.46	1.00		
Unimproved	2	3.8	1.81	1.17		
Toilet was Serviced/Pit Emptied					p = 0.61	<i>Kruskal-Wallis test by ranks</i>
In the last month	3	5.8	1.17	0.83		
Between 1 month and 1 year	18	34.7	1.10	0.91		
Between 1 year and 5 years	4	7.7	1.54	1.00		
Never	27	51.9	1.31	0.84		
Toilet Age					p = 0.15	<i>Spearman's rank correlation (ρ = -0.21)</i>
Visible feces observed around the toilet/latrine					p = 0.13	<i>Wilcoxon signed-rank test</i>
No	22	42.3	1.59	1.08		
Yes	30	57.7	1.00	0.55		
Soap present in toilet/ latrine					p = 0.76	<i>Wilcoxon signed-rank test</i>
No	46	88.5	1.25	0.86		
Yes	6	11.5	1.26	0.91		
Number of Users					p = 0.6	<i>Kruskal-Wallis test by ranks</i>
1 – 5	27	51.9	1.12	0.74		
6 – 10	22	42.3	1.41	1.00		
> 11	3	5.8	1.15	0.81		
Number of Users Under Five					p = 0.43	<i>Wilcoxon signed-rank test</i>
0	34	65.4	1.21	0.81		
≥ 1	18	34.6	1.31	0.96		
Incidence of diarrhea					p = 0.36	<i>Kruskal-Wallis test by ranks</i>
In the last 7 days	6	11.5	1.92	1.0		
Within last month	8	15.4	1.00	0.53		
Within last 6 months	7	13.5	1.12	0.59		
In more than 6 months	31	59.6	1.21	0.92		
Incidence of respiratory symptoms in the last 7 days					p = 0.83	<i>Wilcoxon signed-rank test</i>
No	17	32.7	1.24	0.84		
Yes	35	67.3	1.25	0.878		
Chicken/Ducks					p = 0.64	<i>Wilcoxon signed-rank test</i>
<10	37	71.2	1.29	0.90		
≥10	15	28.8	1.15	0.77		
Cattle					p = 0.31	<i>Wilcoxon signed-rank test</i>
No	26	50	1.40	0.96		
Yes	26	50	1.10	0.74		

768 **Table 2.** Distribution of the 175 antibiotic-susceptible and -resistant *E. coli* isolates by source.

Source	No. (%) of susceptible isolates	No. (%) of resistant isolates to one antibiotic in 1 to 3 or more antibiotic categories ^a		
		1	2	3 or more ^b
Soil	13 (56.5)	5 (21.7)	2 (8.7)	3 (13.0)
Human	23 (46.0)	10 (20.0)	6 (12.0)	11 (22.0)
Chicken	22 (43.1)	11 (21.7)	10 (19.6)	8 (15.7)
Cattle	43 (84.3)	7(13.7)	1 (2.0)	0 (0)
Total	101 (57.7)	33 (18.9)	19 (10.9)	22 (12.6)

769 ^aPenicillins, monobactams, third generation cephalosporins, tetracyclines, phenicols and

770 quinolones.

771 ^bResistance to 3 or more antibiotic categories were classified as multidrug resistant.

772 **Table 3.** Distribution of intestinal pathotypes of *E. coli* isolated from soil and fecal samples.

Source	No. <i>E. coli</i>	No. (%) of isolates positive for intestinal pathogenic virulence-associated genes					
		EAEC ^a	EIEC ^b	EPEC ^c	ETEC ^d	STEC ^e	Any IPEC
Soil	23	1 (4.4)	0 (0)	1 (4.4)	0 (0)	0 (0)	2 (8.7)
Human	50	2 (4.0)	0 (0)	2 (4.0)	1 (2.0)	0 (0)	5 (10.0)
Chicken	51	0 (0)	0 (0)	4 (7.8)	0 (0)	0 (0)	4 (7.8)
Cattle	51	0 (0)	0 (0)	1 (2.0)	0 (0)	6 (11.8)	7 (13.7)
Total	175	3 (1.7)	0 (0)	8 (4.6)	1 (0.6)	6 (3.4)	18 (10.3)

773 ^aEAEC: Indicated by the presence of *aat* or *aat* and *aaiC*774 ^bEIEC: Genes *ial* and *ipaH* were not detected.775 ^cEPEC: Indicated by the presence of *eae* or *eae* and *bfp*.776 ^dETEC: Indicated by the presence of *lt*.777 ^eSTEC: Indicated by the presence of *stx1* or *stx1* and *stx2*.

778 **FIGURE LEGENDS.**

779 **Figure 1.** Survival dynamics of four EPEC isolates (15-CH, 24-H, 26-H, and 29-CH) in
780 autoclaved soils. **(a)** Geometric mean \log_{10} CFU per gram of dry soil of four EPEC isolates
781 measured at day 0, 3, 7, 14, 28, 56, and 84 after spiking standard soil. Each symbol represents
782 the geometric mean \log_{10} CFU per gram of dry soil and the error bar indicates the standard
783 deviation of three independent replicates per isolate. Lower limit of detection (LOD) is indicated
784 by the horizontal dotted line. Gravimetric water content (GWC) of the soil at each time point is
785 indicated by the dotted line and the right y-axis. **(b)** Aggregate of the concentration of four EPEC
786 isolates in the standard soil and soils collected from three households (HH-15, HH-29, and HH-
787 34). Each symbol represents the \log_{10} CFU per gram of dry soil for each isolate and their
788 replicates (three independent replicates per isolate); the horizontal line is the geometric mean
789 \log_{10} CFUs per gram of dry soil of all the isolates for each soil type (GWC is indicated) and on
790 each sampling day (day 0, 3, and 7); the dotted line indicates the lower LOD. When the CFU
791 counts were below the lower LOD, the value used to graph correspond to half the lower LOD.

792

793 **Figure 2.** Survival dynamics of *E. coli* 26-H (isolated from human feces, classified as typical
794 EPEC, resistant to third-generation cephalosporins, ESBL producer, and carrier of the CTX-M
795 beta-lactamase) in ten Bangladeshi household soils. Each symbol represents the geometric mean
796 \log_{10} CFU per gram of dry soil and the error bar indicates the standard deviation of three
797 independent replicates per soil at day 0, 7, 14 and 28 (only for two soil). Day (-7) represents the
798 calculated CFU per gram used to seed the autoclaved fraction of the soils; day (0) is the CFUs
799 per gram of dry soil after spiking the non-autoclaved portion with the seeded autoclaved soil
800 (1:19 autoclaved: non-autoclaved ratio). The dotted line indicates the lower limit of detection

801 (LOD). When the CFU counts were below the lower LOD the value used to graph correspond to
802 half the lower LOD.
