

## AN ABSTRACT OF THE THESIS OF

Maxwell K. Wallace for the degree of Doctor of Philosophy in Chemistry  
presented on March 7, 2019.

Title: Enigmatic Quantum Materials: Novel Spin-Orbit Coupled  $4d/5d$  Metal  
Oxides and Intermetallics

Abstract approved: \_\_\_\_\_

Munirpallam A. Subramanian

This dissertation examines unexplored  $4d/5d$  metal oxides and intermetallics projected to have novel quantum states such as topologically insulating, quantum spin liquid, superconducting, and/or thermoelectric behavior. Fundamentally, the aim is to establish novel structure-property relationships of such candidates. Five projects are presented in this dissertation.

A quantum spin liquid (QSL) represents a new state of matter. Unlike conventional magnetic states, such as the ferromagnetic or the antiferromagnetic states, a QSL never enters into a long-range ordered phase with a static arrangement of spins, even at absolute zero temperature. Quantum computation is the most attractive potential application of a QSL. The demonstration by Alexei Kitaev of an exactly solvable QSL model incorporating  $S = 1/2$  spins with anisotropic

interactions on a honeycomb lattice has motivated searches for its experimental realization. Whereas magnetic honeycomb-containing compounds have been extensively investigated in  $3d$  and  $4d$  metal oxides, the strong interaction anisotropy required by Kitaev’s theory has placed a focus on  $5d$  metal oxides, for which spin-orbit coupling (SOC) can be expected. Many  $A_2MO_3$  “honeycomb” layered oxides, where  $A$  is an alkali atom and  $M$  is a  $4d$  or  $5d$  element, show unique electronic and magnetic properties, indicative of SOC. Known  $A_2MO_3$ , however, do not display QSL behavior. Osmium based  $A_2MO_3$  “honeycomb” layered oxides has been of current interest within the solid state community as it is considered to be a candidate Kitaev quantum spin liquid. The first example of Os on a honeycomb structure,  $Li_{2.15(3)}Os_{0.85(3)}O_3$ , is presented. This compound is an off-stoichiometric version of  $Li_2OsO_3$  with the  $\beta$ - $Li_2SnO_3$  structure ( $C2/c$ ) ( $a = 5.09 \text{ \AA}$ ,  $b = 8.81 \text{ \AA}$ ,  $c = 9.83 \text{ \AA}$ ,  $\beta = 99.3^\circ$ ). Neutron diffraction shows large site disorder in the honeycomb layer and X-ray absorption spectroscopy indicates a valence state of Os ( $+4.7 \pm 0.2$ ), consistent with the nominal concentration. A narrow transport band gap of  $\Delta = 243 \pm 23 \text{ meV}$ , a large van Vleck susceptibility, and an effective moment of  $0.85 \mu_B$  is observed. No evidence of long range order is found above  $0.10 \text{ K}$  but a spin glass-like peak in ac-susceptibility is observed at  $0.5 \text{ K}$ . The specific heat displays an impurity spin contribution in addition to a power law  $\propto T^{(0.63 \pm 0.06)}$ . Density functional theory (DFT) applied to  $Li_2OsO_3$  leads to a reduced moment, suggesting incipient itineracy of the valence electrons. Constrained non-collinear moment DFT is applied to an ordered version of  $Li_{2.25}Os_{0.75}O_3$ , finding evidence that Li over stoichiometry leads to Os(4+)-Os(5+) mixed valence. This local pic-

ture is discussed in light of the site disorder and a possible underlying quantum spin liquid state.

The interest in perovskites can be attributed to their wide array of properties, which in turn derives from their compositional and structural flexibility. The framework of the  $A_2MM'O_6$  double perovskite containing  $4d/5d$  elements with strong spin-orbit coupling (SOC) are of interest for the exploration of quantum magnetism. In such systems, the interplay between the electron localizing tendencies of SOC and the delocalizing effects of the large spatial extent of the  $4d/5d$  orbitals has the potential to combine with electronic correlations to produce unusual states. The motivation to study  $Ba_{2-x}La_xYIrO_6$  is twofold: (1) to investigate a mixed  $5d^4/5d^5$  iridate perovskite with noncubic symmetry and with iridium as the sole magnetic ion, and (2) to elucidate the influence of local environment on the magnetism in such systems. As shown by the structural refinements presented,  $a^0a^0a^0$  ( $Fm\bar{3}m$ )  $\rightarrow$   $a^0b^-b^-$  ( $I2/m$ ) octahedral distortion of the  $YO_6$ - $IrO_6$  rock-salt framework occurs with increasing  $x$  to account for the incorporation of smaller  $La^{3+}$  radii. From the magnetic susceptibility measurements, deviations from the proposed mixed valence picture are observed, not only for  $x = 0.2$ , but also on approaching  $x = 0.8$ . For  $x = 0.2$ ,  $\chi_{VV}$  is larger than found for  $x = 0$ .

Frustrated systems populated with large spin-orbit coupled (SOC) ions are an ideal setting for the exploration of exotic states. Among the known frustrated frameworks, the spinel structure has been extensively investigated. Though many spinel systems with  $3d/4d$  elements exist, to our knowledge, an Iridium based spinel oxide has not been reported. Most spinel oxides are known to be insulating

and only two,  $\text{LiV}_2\text{O}_4$  and  $\text{LiTi}_2\text{O}_4$ , are reported as conducting. A frustrated mixed valence system that is metallic and exhibits large SOC is scarce, and if a metallic spinel is close to a correlation driven metal-insulator transition, a novel interplay between the charge carriers and the frustrated spin degree of freedom is anticipated. Here we present the first Iridate spinel:  $\text{Cu}[\text{Ir}_{1.498(1)}\text{Cu}_{0.502(1)}]\text{O}_4$ . Synchrotron XRD refinements reveal a face-centered cubic structure with space group  $Fd\bar{3}m$ . Electrical properties reveal a metallic state within 50~600 K range with a Kondo-effect at  $T < 50$  K.

The “phonon-glass/electron-crystal” approach has been implemented through incorporation of “rattlers” into skutterudite void sites to increase phonon scattering and thus increase the thermoelectric efficiency. Indium filled  $\text{IrSb}_3$  skutterudites are reported for the first time. Polycrystalline samples of  $\text{In}_x\text{Ir}_4\text{Sb}_{12}$  ( $0 \leq x \leq 0.2$ ) were prepared by solid-state reaction under a gas mixture of 5%  $\text{H}_2$  and 95% Ar. The solubility limit of  $\text{In}_x\text{Ir}_4\text{Sb}_{12}$  was found to be close to 0.18. Synchrotron X-ray diffraction refinements reveal all  $\text{In}_x\text{Ir}_4\text{Sb}_{12}$  phases crystallized in body-centered cubic structure (space group:  $Im\bar{3}$ ) with  $\sim 8\%$  antimony site vacancy and with indium partially occupying the  $16f$  site. Unlike known rattler filled skutterudites, under synthetic conditions employed, indium filling in  $\text{IrSb}_3$  significantly increases the electrical resistivity and decreases the Seebeck coefficient ( $n$ -type) while reducing the thermal conductivity by  $\sim 30\%$ . The resultant power factor offsets the decrease in total thermal conductivity giving rise to a substantial decrease in ZT. Principal thermoelectric properties of  $\text{In}_x\text{M}_4\text{Sb}_{12}$  ( $\text{M} = \text{Co}, \text{Rh}, \text{Ir}$ ) phases are compared. As iridium is a  $5d$  transition metal, zero field cooled (ZFC) magnetiza-

tion were performed to unravel the effect of spin-orbit interaction on the electronic properties. These results serve to advance the understanding of filled skutterudites, and provide additional insight on the less explored smaller “rattlers” and their influence on key thermoelectric properties.

The solid solution series  $\text{Li}_2\text{Ir}_{1-x}\text{Rh}_x\text{O}_3$  is synthesized for several values of  $x$  between 0 and 1. The compounds possess a monoclinic layered structure (space group  $C2/m$ ) throughout the solid solution range with the lattice constants following Vegard’s relationship. Magnetization and resistivity data below room temperature are presented. The effective magnetic moment ( $\mu_{eff}$ ) is reduced below the value obtained by interpolating between the end-members, presumably due to nearest neighbor charge exchange leading to non-magnetic  $\text{Ir}^{5+}/\text{Rh}^{3+}$  pairs. Surprisingly, the degree of reduction of  $\mu_{eff}$  cannot be explained by a random mixture of Ir and Rh and is strongly asymmetric around  $x = 0.5$ . This anomalous moment reduction possibly results from the difference in on-site Coulomb repulsion between Ir and Rh ions.

## ACKNOWLEDGEMENTS

I would like to express my sincere gratitude to Dr. Mas Subramanian for serving as my PhD advisor. His support, expertise, dedication, and enthusiasm have been an inspiration. I am grateful to all the past and present members of Dr. Subramanians group I've had the pleasure of working with. I would like to thank Dr. Jun Li for her helpful discussions on crystallography. The knowledge and skills I learned during my time in Dr. Subramanians lab have helped me become a better researcher and solid state chemist and I will continue to utilize them in the future. I would like to thank Dr. Arthur Ramirez for all of his helpful discussions and support with constructing the manuscripts. I would also like to acknowledge additional collaborators and national lab scientists I have had the privilege of working with: Dr. Warren Pickett, Dr. Daniel Haskel, Dr. Joshua Telser, Dr. Ashfia Huq, Dr. Saul Lapidus, Dr. Katharine Page, and Dr. Joerg Neufeind. I would like to thank my committee members for serving on the graduate committee. The time they spent critiquing the thesis and providing helpful comments were greatly appreciated. I would like to thank Dr. Anthony Diaz for igniting my passion for chemistry and his overall support. I would like to express my sincere appreciation to my parents, Ellen and Jeff, for all of their support. Finally I would like to express my sincere appreciation to my wife, Bridget, for her patience, understanding, and encouragement throughout my graduate career.

## CONTRIBUTION OF AUTHORS

**Chapter 6:** M.A. Subramanian and A.P. Ramirez conceived the interest. M.K. Wallace designed, constructed, and carried out the synthesis. P.G. LaBarre and M.K. Wallace collected electronic and magnetic properties. M.K. Wallace and J. Li performed TOF neutron refinements and M.K. Wallace performed stacking fault modeling. S.T. Pi and W.E. Pickett performed DFT calculations. D. Haskel collected and analyzed XAS measurements. A.P. Ramirez, W.E. Pickett, D.S. Dessau, and P.G. LaBarre analyzed and discussed electronic properties and M.A. Subramanian, M.K. Wallace, and J. Li discussed structure characterization. M.K. Wallace, A.P. Ramirez, and W.E. Pickett constructed manuscript. Remaining authors provided helpful feedback on manuscript.

**Chapter 7:** M.K. Wallace conceived the interest. M.K. Wallace and S. Svadlenak designed, constructed, and carried out the synthesis. M.K. Wallace and S. Svadlenak collected electronic properties and P.G. LaBarre collected magnetic properties. M.K. Wallace and S. Svadlenak performed refinements on lab XRD and M.K. Wallace performed refinements on TOF neutron diffraction data. P.G. LaBarre and A.P. Ramirez interpreted magnetic properties. M.K. Wallace and A.P. Ramirez constructed manuscript. Remaining authors provided helpful feedback on manuscript.

**Chapter 8:** M.K. Wallace conceived the interest. M.K. Wallace designed, constructed, and carried out the synthesis. P.G. LaBarre and M.K. Wallace col-

lected electronic and magnetic properties. M.K. Wallace performed refinements on lab XRD and synchrotron XRD. A.P. Ramirez and P.G. LaBarre interpreted magnetic properties. J. Telsler collected and interpreted EPR spectroscopy measurements. M.K. Wallace and A.P. Ramirez constructed manuscript. Remaining authors provided helpful feedback on manuscript.

**Chapter 9:** M.A. Subramanian and M.K. Wallace conceived the interest. M.K. Wallace designed, constructed, and carried out the synthesis. M.K. Wallace collected electronic and thermal properties and A.P. Ramirez collected magnetic properties. M.K. Wallace performed refinements on lab XRD and synchrotron XRD. M.A. Subramanian, M.K. Wallace, J. Li, and A. Sleight discussed structure characterization. M.K. Wallace constructed manuscript. Remaining authors provided helpful feedback on manuscript.

**Appendix C:** M.A. Subramanian conceived the interest. S.L. Kumari and M.K. Wallace designed, constructed, and carried out the synthesis. S.L. Kumari and M.K. Wallace collected electronic properties and J.T. Barnes and B. Tong collected magnetic properties. A.P. Ramirez interpreted electrical properties. M.K. Wallace performed refinements on lab XRD and TOF neutron diffraction data. M.K. Wallace performed stacking fault modeling. S.L. Kumari, M.K. Wallace, and A.P. Ramirez constructed manuscript. Remaining authors provided helpful feedback on manuscript.

4.7	Illustrations of (a) the ideal cubic $ABX_3$ perovskite framework with B-cations (black spheres) residing in octahedral sites and A-cations (white spheres) residing in a 12-coordinated dodecahedral environment, (b) three-dimensional cubic network of corner-sharing $BX_6$ octahedra, with the A-cation residing in the center of a cube defined by eight corner-sharing octahedral units, (c) cubic close-packed $AX_3$ arrangement with 1/4 of the octahedral holes filled with B-cations, and (d) double perovskite 1:1 rock salt ordered $A_2BB'X_6$ . . . . .	72
4.8	Illustration of 1:1 and 1:2 B-site cation ordering sequence in $AA'BB'X_6$ (A-cations and X-anions are removed for clarity). . . . .	73
4.9	Cation ordering schemes in perovskites. From top to bottom rock salt, layered ordering, and columnar ordering are shown for B-site ordering in $A_2BB'X_6$ perovskites (left) and for A-site ordering in $AA'B_2X_6$ (right) perovskites. . . . .	75
4.10	The anion environment in a primitive $ABX_3$ perovskite and in a rock salt ordered $AA'B_2X_6$ perovskite, where $AA'$ , B, and X are green/blue, grey, and red, respectively. . . . .	76
4.11	Mechanisms of octahedral distortion throughout the corner sharing B/B'X <sub>6</sub> framework. . . . .	78
4.12	View looking down the c-axis of $a^o a^o c^-$ and $a^o a^o c^+$ with the B-site cations located at the center of the grey octahedral sites and A-site cations shown as white spheres. . . . .	80
4.13	Skutterudite crystal structure shown as (a) a repeated corner-sharing $MX_6$ arrangement and (b) cube-forming M atoms with three fourths of the void sites filled with $X_4$ Zintl polyanions. . . . .	82
5.1	Schematic of a $AM_2$ “honeycomb” layer along the $a - b$ plain ( $C2/m$ unit cell) and the new idealized DIFFaX hexagonal unit cell (red dash) with black and blue representing the M transition metal and the A-cation, respectively. . . . .	86

## LIST OF FIGURES (Continued)

<u>Figure</u>	<u>Page</u>	
5.2	Illustration of the close packing stacking arrangement of oxygen (red), A-cations (blue), and M-cations (black) for a honeycomb $A_2MO_3$ down the $c$ -axis. Top illustrations represent all atoms in space-filling form with the bottom illustrations representing only the A- and M-cations for a single honeycomb ring. . . . .	88
5.3	Possible stacking sequences between $AM_2$ layers, based on the given DIFFaX unit cell described in the text, with $[\frac{1}{3}, 0, 1]$ transition vector ( $R_1$ ) representing the ideal $A_1B_1C_1$ stacking sequence of $A_2MO_3$ ( $C2/m$ ), and transition vectors $[\frac{1}{3}, \frac{1}{3}, 1]$ and $[0, \frac{1}{3}, 1]$ ( $R_2$ and $R_3$ ) describing stacking fault contribution (a). Illustrations representing the influence of varying the vector assignment between three DIFFaX unit cells are shown (b-d), with (b) representing the ideal $A_1B_1C_1$ stacking sequence of monoclinic $A_2MO_3$ ( $C2/m$ ). . . . .	89
5.4	A comparison of XRPD of $Li_2IrO_3$ ( $C2/m$ ) and the calculated XRPD of $Li_2IrO_3$ DIFFaX model with $\alpha_1 = 0.98$ and $\alpha_2 = \alpha_3$ . For the model presented, Li-Ir site disorder within the $LiIr_2$ layers was implemented with $Ir(4g)/Li(2a)$ occupancies set to 0.85. . . . .	90
5.5	Calculated XRPD of $Li_2IrO_3$ DIFFaX model with $\alpha_1$ from 1 to 0.5 and $\alpha_2 = \alpha_3$ . For the model presented, Li-Ir site disorder within the $LiIr_2$ layers was implemented with $Ir(4g)/Li(2a)$ occupancies set to 0.85. . . . .	91
5.6	Illustration of the FAULTS single layer down the $c$ -axis. The M-cation and oxygen are represented as black and red spheres, respectively. Lithium residing within the honeycomb rings are represented as green spheres and lithium beneath the honeycomb layers as blue spheres. . . . .	92
6.1	Left: $Li_2MO_3$ (M= 4d or 5d element) structure as alternating Li and $LiM_2$ layers. Right: Viewed along the $c$ axis the $LiM_2$ layer, where $MO_6$ edge-sharing octahedra form the honeycomb lattice. Blue, green, and red spheres represent lithium, metal, and oxygen atoms respectively. . . . .	97

Figure	Page
6.10 XAS measurements at the Os $L_{2,3}$ absorption edges on $\text{Li}_{2.15}\text{Os}_{0.85}\text{O}_3$ and three reference compounds with known oxidation state. . . . .	110
6.11 Top: High temperature resistivity and Seebeck coefficient data of $\text{Li}_{2.15}\text{Os}_{0.85}\text{O}_3$ sample from 350 to 600 K. Bottom: Resistivity versus temperature for $\text{Li}_{2.15}\text{Os}_{0.85}\text{O}_3$ in the range 200 – 600 K versus inverse temperature. The low and high temperature measurements were performed in different apparatuses on samples from the same growth run. To assure continuity at $T = 300$ K, the data have been rescaled for the low temperature measurement due to its greater uncertainty in the geometric factor. . . . .	111
6.12 Top: DC-Susceptibility $\text{Li}_{2.15}\text{Os}_{0.85}\text{O}_3$ versus temperature. Also shown is the inverse susceptibility after subtracting a van Vleck term as described in the text. Bottom: ac-susceptibility versus temperature at different values of applied magnetic field. The curves have been offset vertically by 0.0020, 0.0032, 0.0044, and 0.0056 emu for $H = 88, 126, 500,$ and $1000$ G respectively, for clarity. . . . .	113
6.13 The specific heat $C(T)$ of $\text{Li}_{2.15}\text{Os}_{0.85}\text{O}_3$ in various applied fields, measured using a Physical Property Measurement System. Bottom: Plotting $C/T$ vs. $T^2$ from the Einstein-Debye model should result in a linear correlation if no phase/electronic transition occurs. . . . .	114
6.14 Top: Impurity spins modeled with a Schottky anomaly. Bottom: Specific heat after removing the impurity contribution. . . . .	117
6.15 Plot of bands in the Os $t_{2g}$ region of 25% Li-substituted $\text{Li}_2\text{OsO}_3$ on the Os honeycomb sublattice, with energy zero (horizontal red dashed line) denoting the gap region. The fatbands plots emphasize the Os 5d character on (a) the Os[0] site with no Li neighbor, (b) the Os[1] site with one Li neighbor, and (c) the Os[2] site with two Li neighbors. While Os[0] and Os[1] show some differences, Os[2] is qualitatively different. . . . .	121
7.1 The ideal cubic $\text{A}_2\text{MM}'\text{O}_6$ double perovskite with blue, green/purple, and red representing A-site, M/M'- site, and oxygen, respectively.	127

## LIST OF FIGURES (Continued)

<u>Figure</u>	<u>Page</u>
7.2 XRD patterns of $\text{Ba}_{2-x}\text{La}_x\text{YIrO}_6$ ( $0 \leq x \leq 0.6$ ) samples shown from $15\text{-}110^\circ 2\theta$ . A small presence of $\text{La}_2\text{O}_3$ impurity exists for $x \leq 0.6$ samples (asterisks). Trace $\text{Y}_2\text{O}_3$ impurity phase was detected in the diffraction pattern upon magnification for all samples (diamonds).	131
7.3 Cell edges a, b, and c vs $\text{La}^{3+}$ content $x$ in $\text{Ba}_{2-x}\text{La}_x\text{YIrO}_6$ . Lab XRD cell parameters are plotted by nominal $\text{La}^{3+}$ content $x$ . TOF neutron cell parameters are plotted by refined $\text{La}^{3+}$ content $x=0.56$ .	132
7.4 Illustration of $\text{A}_2\text{MM}'\text{O}_6$ rock salt M-site ordered double perovskite structure looking down the c-axis of $a^0a^0a^0$ ( $Fm\bar{3}m$ ), $a^0a^0c^-$ ( $I4/m$ ), and a-b plane of $a^0b^-b^-$ ( $I2/m$ ) tilt systems. Here, A-site cations are represented as blue spheres and M/M' cations reside separately within the green and purple polyhedral sites. . . . .	133
7.5 TOF Neutron refinement of nominal compositions $\text{Ba}_2\text{YIrO}_6$ (top) and $\text{Ba}_{1.4}\text{La}_{0.6}\text{YIrO}_6$ (bottom). Observed (black crosses) and calculated (solid red line) profiles, background (green), and difference curve ( $I_{obs}-I_{calc}$ ) (blue) are shown for each refinement. The vertical bars indicate the expected reflection positions with black, pink, and teal representing $\text{Ba}_{2-x}\text{La}_x\text{YIrO}_6$ , $\text{Y}_2\text{O}_3$ ( $Ia\bar{3}$ ), and $\text{La}_2\text{O}_3$ ( $P3\bar{m}1$ ) phases respectively. Resulting stoichiometric identities and $wR_p$ are represented. . . . .	135
7.6 A portion of the $\text{Ba}_2\text{Y}_{0.955(8)}\text{IrO}_{5.964(2)}$ ( $Fm\bar{3}m$ ) and $\text{Ba}_{1.442(4)}\text{La}_{0.558(4)}\text{Y}_{0.953(2)}\text{IrO}_{5.952(8)}$ ( $I2/m$ ) unit cells from TOF neutron refinements with barium-lanthanum, yttrium, iridium, and oxygen thermal ellipsoids represented as blue, green, purple, and red respectively. . . . .	140
7.7 Temperature dependent resistivity (top) and Seebeck coefficient data (bottom) of $\text{Ba}_{2-x}\text{La}_x\text{YIrO}_6$ samples ( $0 \leq x \leq 0.6$ ) from 300 to 600 K. . . . .	141
7.8 Temperature dependent, low temperature resistivity plots (top/middle) for $\text{Ba}_{2-x}\text{La}_x\text{YIrO}_6$ samples ( $0 \leq x \leq 0.6$ ) and the differential activation energy determined by differentiating $\ln(\rho)$ with respect to $(k_B T)^{-1}$ (bottom) from 75 to 300 K. . . . .	142

## LIST OF FIGURES (Continued)

# Chapter 1: Fundamentals of Solid State Chemistry: Synthesis, Material Properties, and Characterization Methods

## 1.1 Introduction

Solid-state chemistry is the study of the synthesis, structure, and properties of solid phase materials with a focus on the synthesis of novel materials and their characterization. It therefore has a strong overlap with solid-state physics, crystallography, mineralogy, ceramics, metallurgy, and materials science. Pertinent solid state fundamentals will be exploited in this chapter. Here, a brief overview of pertinent synthesis techniques, material properties, and structural and electronic characterization methods will be introduced to provide the reader with the basic knowledge to grasp the research presented in this dissertation.

## 1.2 Synthesis Methods

A variety of synthesis methods were employed in this dissertation. The standard solid-state synthesis method, crystal growth flux method, hydrothermal method, sealed quartz tube method, and ion exchange method were employed. A brief overview of each method will be addressed.

### 1.2.1 Standard Solid-State Synthesis

The traditional standard solid-state synthesis method, also referred to as “shake-and-bake” method relies on elevated temperatures for atomic diffusion and reaction [1]. This synthesis route begins with a stoichiometric amount of powdered starting materials, typically metal oxides or metal carbonates. These are mechanically ground together in a mortar and pestle, or ball milled, and then pressed into a pellet before heat treatment. This treatment provides maximum contact between particles, enabling atomic diffusion between the starting reagents. The corresponding sample is then heated to temperatures anywhere from 300 - 1500 °C. The target temperature is dictated by the elemental composition of the sample, and properties such as volatility, melting point, and reactivity must be taken into consideration. Subsequent grinding, pressing, and heating processes may be needed for reaction completion. The combination of kinetics and thermodynamics can explain the success of such a method and can be thermodynamically predicted through the consultation of phase diagrams. High-temperature synthesis is needed to overcome diffusion barriers and lattice enthalpies, and diffusion begins at the interfaces between particles of starting reagents, with product formation occurring at the interface. For this reason intermediate grinding between successive heating intervals are crucial for complete product formation, as it creates new interfaces of unreacted starting material for product formation.

### 1.2.2 Molten Salt Ion Exchange

The molten salt ion exchange method relies on the topotactic exchange of ions in a structure [1]. In such a reaction, cations from the host phase are exchanged for those from the surrounding phase. Molten salt ion exchange uses a water-soluble salt with a low melting point, such as alkali halides or nitrates. For the exchange reaction, the parent compound is combined with the alkali salt in an excess molar ratio of the salt. Once thoroughly combined and mixed, the mixture is placed in an appropriate reaction vessel and heated above the melting point of the salt. Once in a liquid state, diffusion of the alkali cations into the host structure can occur, with counter-diffusion of host structure cations into the molten liquid phase. After cooling, any excess alkali salt or salt from the exchanged host cation can be removed by washing with water and/or using mild acidic conditions.

### 1.2.3 Crystal Growth Flux Method

There are a wide variety of crystal synthesis techniques; the most common method is the flux method. Flux method can be achieved when the components of the desired substance are dissolved in a solvent (flux) [1]. This flux method takes place in a crucible made of highly stable, non-reactive material such as an aluminum oxide crucible or a sealed quartz ampule. By keeping the constituents of the desired crystal and the flux at a temperature slightly above the saturation temperature, an over-saturated solution can be achieved. By cooling the crucible slowly, crystal formation can begin by spontaneous nucleation. As material precipitates out of

the solution with slow cooling, the amount of solute in the flux decreases and the saturation temperature lowers. This process repeats itself as the furnace continues to cool until the solution reaches its melting point.

#### 1.2.4 Hydrothermal Synthesis

The synthesis of single crystals can be achieved using the hydrothermal synthesis method [1]. This method depends on the solubility of minerals in hot water under high pressure. Crystal growth using this method can be achieved using an apparatus consisting of a steel pressure vessel called an autoclave, in which the reactants are supplied along with water or nonaqueous solvents as a reaction medium. If the non-aqueous solvents are utilized as reaction medium, this approach is defined as a solvothermal method; whereas, in the presence of water, it is known as hydrothermal process. A temperature gradient is achieved between the opposite ends of the growth chamber. At the hotter end the nutrient solute dissolves, while at the cooler end precipitates form, growing the desired crystal.

#### 1.2.5 Sealed Quartz Tube Ampule Method

Solid state reactions in which air sensitivity is a major concern can be achieved using the sealed quartz tube ampule method [2]. Here, a sample is placed at the bottom of a sealed quartz tube and a vacuum using a turbo pump system is applied to evacuate the air. Pressures within the quartz tube generally are  $\sim 10^{-4}$  Torr.

An  $\text{H}_2/\text{O}_2$  torch can be used to seal/cut the quartz tube. The corresponding quartz tube can then be heated to desired temperature.

## 1.3 Structural Characterization

### 1.3.1 Introduction

A variety of diffraction methods were employed in this dissertation. Here, fundamentals of diffraction and key powder diffraction techniques will be addressed.

### 1.3.2 Fundamentals of Diffraction

When electromagnetic radiation passes through a crystalline lattice, the atomic positions can act as scattering centers and coherent and incoherent scattering can occur. For an incident X-ray beam with a fixed wavelength comparable to atomic spacings, the electronic cloud will distort, and the movement of these charges re-radiates waves with the same frequency. This phenomenon is known as elastic scattering [3]. Constructive interference occurs when the distance between the adjacent Miller planes,  $d$ , is an integral multiple of the wavelength,  $\lambda$ , and can ultimately be explained by Bragg's law (Figure 1.1) [3].

By altering the incident angle of the X-ray beam with a fixed wavelength, certain Miller planes with different  $d$ -spacing will satisfy Bragg's law, and therefore coherent diffraction will occur, resulting in a diffraction pattern. A diffraction pattern is not a direct representation of the crystal lattice. It is, however, a repre-

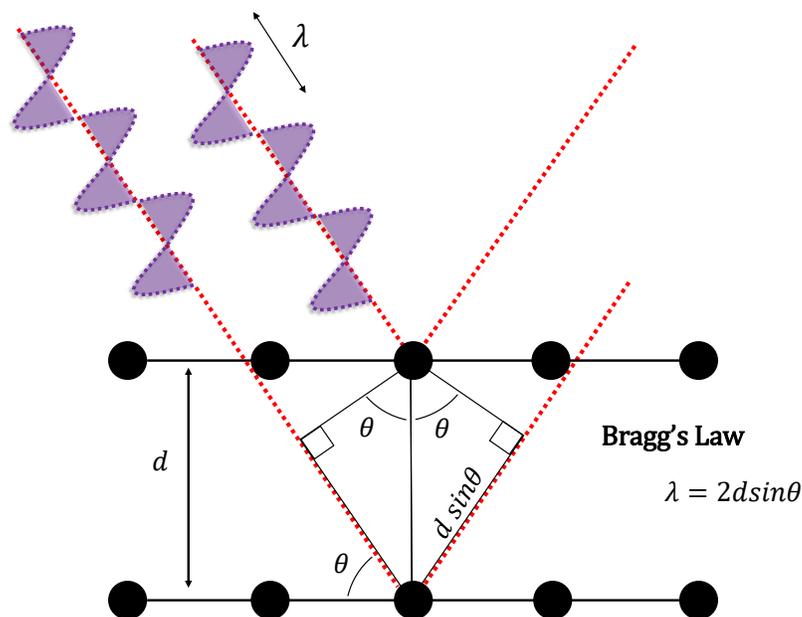

Figure 1.1: Constructive interference occurs when the waves reflected from adjacent scattering planes remain in phase. This occurs when the distance between the adjacent planes,  $d$ , is an integral multiple of the wavelength,  $\lambda$ , and can ultimately be explained by Bragg's law.

sentation of the reciprocal lattice. For every real lattice there is a reciprocal lattice. Therefore, the relationship between the crystal lattice and a diffraction pattern is linked by the reciprocal lattice via a Fourier transform. The families of planes in a crystal lattice can be represented by their normals, which are specified as vectors and which can be used to define a pattern of points, with each point representing a family of planes [3]. These points described by the normal vectors characterize the reciprocal lattice. Thus, the crystal axes can be defined in terms of the normal to crystal faces with each point in reciprocal space representing a set of planes within the crystal lattice.

### 1.3.3 Powder Diffraction Techniques

#### 1.3.3.1 X-ray Diffraction

A popular instrument for the study of crystalline materials is powder X-ray diffraction (PXRD). For most laboratory X-ray diffraction instruments, the Bragg-Brentano focusing geometry is the most common diffractometer layout [3]. The source of X-ray radiation for PXRD is commonly an X-ray tube or a synchrotron particle accelerator at a national lab.

Laboratory X-ray diffractometers utilize an X-ray tube consisting of a metal target, which acts as the anode (typically copper), and a source of electrons (typically a tungsten filament) acts as the cathode. To generate X-rays, a large voltage potential is applied across the anode and the cathode ( $\sim 30$  kV), resulting in a flow of high speed electrons from the filament to the metal target [3]. Upon collision with the metal target, a continuous spectrum of X-rays is generated. This continuous spectrum of radiation is a result of the rapid changes in kinetic energy of electrons interacting with the target, and is called white radiation. For a copper anode, the incident electrons bombarding the anode surface have enough energy to ionize the  $1s$  ( $K$  shell) electrons, and an electron in the  $2p$  or  $3p$  orbital immediately relaxes down to occupy the vacant state, resulting in a release of X-ray radiation. The  $2p \rightarrow 1s$  transition has a wavelength of  $1.5418 \text{ \AA}$  and is called  $K_\alpha$ . The  $3p \rightarrow 1s$  transition has a wavelength of  $1.3922 \text{ \AA}$  and is called  $K_\beta$ . For a copper anode, nickel foil is a very effective filter as the energy required to ionize  $1s$  electrons corresponds to a wavelength of  $1.488 \text{ \AA}$ , which lies in energy between  $K_\alpha$

and  $K_\beta$  [3].

X-rays from synchrotron sources are emitted when charged particles (typically electrons) are traveling at near relativistic speeds and are forced to change direction on passing through a magnetic field. Such synchrotron storage rings exist at national labs such as Argonne National Lab. Synchrotron X-rays have several advantages, such as very high intensity beams that are continuous over the complete spectral range and the beams are accurately parallel, resulting in high resolution in powder diffraction data [3].

### 1.3.3.2 Neutron Diffraction

For both neutron and X-ray diffraction, the concept of diffraction is essentially the same, as defined by Bragg's Law. Neutron diffraction can be used to determine the structural and atomic parameters of materials that have both light and heavy atoms present [4]. Neutron diffraction is ideal to characterize most metal oxide structures as oxygen has a neutron scattering length comparable to most heavy metals [4]. Neutron diffraction can also provide contrast between atoms with similar atomic numbers, as well as contrast between different isotopes of the same atom. Neutrons exhibit a dipole moment and can therefore interact with unpaired electrons in a material. Thus, magnetic ordering will be apparent in neutron diffraction. Ferromagnetic ordering in a material results in a change in the peak intensity of peaks already present, whereas antiferromagnetic ordering results in the emergence of new peaks [4]. Neutrons can be generated through either a

spallation process or nuclear fission, and experiments can be performed at either a spallation source or reactor, respectively. Neutrons at a reactor have the advantage of better resolution at higher  $d$ -spacing due to singular monochromatic neutron wavelength. Neutrons produced at a spallation source have a higher incident flux as more neutrons with appropriate energy are released via spallation than fission. In a spallation process, a metal target is bombarded by pulses of a proton beam, and the neutrons are released in pulses with an array of kinetic energy. Recall, the de Broglie equation relates the wavelength,  $\lambda$ , of a system with mass (neutron) to its momentum,  $mv$ . For the spallation process, collector banks are oriented at fixed positions relative to the incoming neutron beam and the sample. Thus, by timing a neutron over a fixed path length, its velocity, and consequently its wavelength, can be measured. As such, spallation radiation is called time-of-flight (TOF). For each collector bank with a fixed position and therefore fixed angle relative to the incoming neutron beam, only certain neutrons with a kinetic energy can satisfy certain  $d$ -spacings associated to Miller planes. Thus, multiple banks of data are needed to refine the crystal structure. Fixed wavelength neutron diffraction and TOF neutron experiments were collected at National Institute of Standards and Technology (NIST) and the Spallation Neutron Source, Oakridge National Laboratory (SNS-ORNL), respectively.

### 1.3.4 Inductively Coupled Plasma - Optical Emission Spectrometry

Inductively coupled plasma – optical emission spectroscopy (ICP – OES) is an analytical technique that can be used to accurately determine the concentration of trace amounts of metals in a solution [5]. ICP – OES utilizes an argon plasma to excite atoms or ions which emit characteristic radiation upon relaxation. The intensity of this from the sample radiation is compared to a calibration curve of previously measured intensities obtained from solutions with known concentrations of the metal in question.

### 1.3.5 Thermogravimetric Analysis

Thermogravimetric analysis (TGA) can provide useful insight into the processes observed in a sample, such as the mass gained during a reaction procedure, the mass lost during a dehydration process, sample decomposition, etc. Such TGA methods delicately measure the mass of a sample as a function of temperature or time [1].

### 1.3.6 Iodometric Titration

Iodometric titration is a redox titration process that involves direct titration using sodium thiosulfate as the titrant [6]. This titration method can be used to determine the concentration of an oxidising agent in solution and to ultimately establish the oxidation state of a metal within a metal oxide structure (assuming

the metal oxide sample can be dissolved in a acidic solution). To a known volume of sample, an excess known amount of iodide ( $I^-$ ) is added. Based on the reduction potentials, iodide will be oxidized by the oxidizing agent to produce triiodide ions ( $I_3^-$ ), which produces a dark brown color in solution. The reduction reaction of  $I_3^-$  and thiosulfate are provided below [6].

Based on the reduction potentials, thiosulfate acts as a reducing agent, thus reducing the formation of  $I_3^-$  back to iodide  $I^-$ , producing a colorless solution.

Thus, the color change represents the end-point of the reaction and from the known amount of sodium thiosulfate with a known concentration required, the concentration of an oxidising agent in solution can be determined; this will ultimately establish the oxidation state of a metal within a metal oxide structure.

### 1.3.7 X-ray Absorption Spectroscopy

For X-ray Absorption Spectroscopy (XAS), X-rays of a narrow energy resolution are shone on the sample and the incident and transmitted X-ray intensity is recorded as the incident X-ray energy is incremented [7]. When a beam of monochromatic X-rays passes through matter, the beam intensity decreases due to interaction with the atoms in the material. Thus, XAS is the measurement of the X-ray absorption coefficient of a material. For X-rays of sufficient energy,

an incoming photon interacts with a deep-core electron; a  $s$  electron is excited for a  $K$ -edge spectrum or a  $p$  electron is excited for a  $L$ -edge spectrum [7]. The deep-core electron is promoted to some unoccupied state above the Fermi energy, and leaves behind a core-hole. A short time later (femtoseconds), the core state is filled via one of two mechanisms: (1) a higher-energy electron decays into the core-hole and emits a photon, or (2) the energy from the higher-lying electron can be used to emit an Auger electron. Since each element has its own edge energy, an element's identity and valence can be determined within a sample using XAS methods.

## 1.4 Electronic Properties of Materials

All elements contain discrete electronic energy levels which are characterized by atomic wave functions. The electronic interaction between atoms within a crystal lattice produces unique delocalized electronic states. The occupied delocalized states form an electronic energy band called the valence band (VB). The unoccupied delocalized states form an electronic energy band called the conduction band (CB). The band structure can be described from either the 'chemical approach' or the 'physical approach' [8]. The more basic 'chemical approach' is to take Molecular Orbital (MO) theory, as it is typically applied to small, finite-sized molecules, and extend it to infinite 3D structures. As shown in Figure 1.2, with an increase in atomic orbitals, the MO states become close enough in energy such that the bonding MO's form the valence state continuum and the antibonding MO's form

the conduction band continuum.

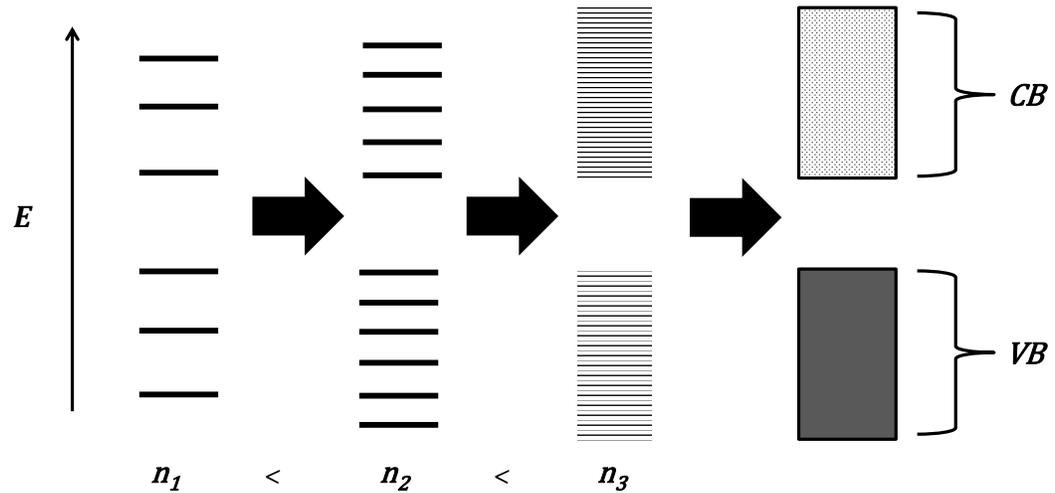

Figure 1.2: A schematic of  $n$  atomic orbitals combining to form MO states, where  $n_1 < n_2 < n_3$ . For  $n_3$ , the MO states are close enough in energy and occupied (VB) and unoccupied (CB) bands exist.

The ‘physical approach’ of band theory is to consider the energy and wavelength of electrons in a solid [8]. The analogy with the quantum mechanical problem of a particle in a box is applied where the energy levels that the electrons occupy are quantized and filled from the bottom of the well up with a total of two electrons per level. The potential within the crystal (or potential well) is periodic, in which the electrons pass through a minimum at the positions of the nuclei and a maximum between the nuclei. The Schrodinger equation that describes such a periodic potential function shows only certain bands of energies are permitted for the electrons. Such forbidden energies correspond to electron wavelengths that do not

satisfy Bragg's law and ultimately leads to discontinuities in the energy-momentum diagrams with forbidden energy levels describing the band gap [8].

### 1.4.1 Characterization of Metals, Semiconductors, and Insulators

If the difference in energy between the lowest unoccupied and highest occupied delocalized states (band gap,  $E_g$ ) is less than  $\sim 0.3$  eV, the material is considered metallic (Figure 1.3 (A)) [9]. If  $E_g$  is within  $\sim 0.3$  to 3 eV, the material is considered a semiconductor (Figure 1.3 (B)). Thermal energy ( $\sim 300$  K) can promote a small portion of electrons with  $k_b T$  kinetic energy to lower unoccupied states for a material. For insulating material,  $E_g$  is large enough ( $> 3$  eV) that a crystal system at  $\sim 300$  K does not provide enough energy to promote electrons to the CB (Figure 1.3 (C)).

The value of the electrical conductivity can, in part, characterize if the material is a metal, semiconductor, or insulator. Table 1.1 below defines the approximate electrical conductivity range for each material type [9].

Table 1.1: Typical values of electrical conductivity of metals, semiconductor, and insulators.

Material	$\sigma$ ( $\Omega^{-1} cm^{-1}$ )
Metal	$10^{-1} - 10^5$
Semiconductor	$10^{-5} - 10^2$
Insulator	$< 10^{-12}$

Though the conductivity values presented in Table 1.1 show a clear distinction between a metal and an insulator, establishing if a material is a metal or semicon-

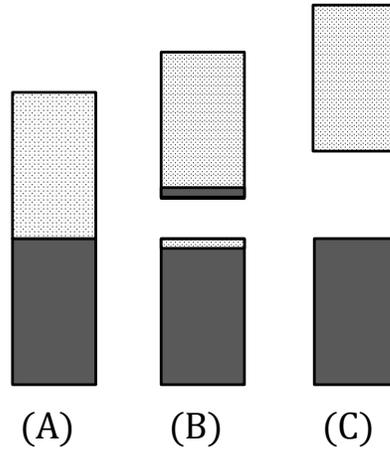

Figure 1.3: Band state schematic of a metal (A), semiconductor (B), and insulator (C).

ductor is not as straightforward. For electrical conduction in semiconductor and insulators to occur, electrons must be promoted across the band gap. In metals, however, there is no band gap. For all materials, electron–phonon collisions contribute to the overall resistivity, meaning that with an increase in temperature, an inherent increase in the electrostatic interactions between mobile electrons and lattice vibrations will occur [9]. For semiconductors and insulators, increasing the temperature means more electrons with adequate  $k_bT$  kinetic energy can occupy the conduction band, outweighing the electron–phonon collision contribution and therefore an increase in the overall electrical conductivity is observed. In metals, electron–phonon collisions dominate, thus showing a decrease in electrical conductivity with increasing temperature. Thus, the trend in electrical resistivity versus temperature can, in part, characterize if the material is a semiconductor or a metal.

### 1.4.2 Modeling the Electronic Properties

In a typical insulator,  $E_g$  is temperature-independent and much larger than  $k_bT$ . Therefore the Arrhenius expression (1.1) can be applied and  $\ln(\rho)$  scales linearly with  $T^{-1}$  in which the slope equates to  $E_g$  [10].

$$\rho \propto e^{(E_g/k_bT)} \quad (1.1)$$

If the energy gap is temperature-dependent, a different behavior known as variable-range hopping (VRH) appears (1.2) in  $d$  dimensions [10].

$$\rho \propto \exp\left(\frac{E_g}{k_bT^{1/(d+1)}}\right) \quad (1.2)$$

The dimensionality,  $d$ , describes the dimension of conductivity throughout the material. Plotting  $\ln(\rho)$  versus  $T^{-1/(d+1)}$  provides the “pseudogap” derived from the slope.

### 1.5 Thermal Transport Properties

Thermal conductivity can be described as the transport of energy in the form of heat through a body of mass with a temperature gradient [9]. Heat always flows toward the lower temperature portion of a material (second law of thermodynamics) (Figure 1.4).

$$\frac{dQ}{dt} = Q = \lambda A \frac{T_2 - T_1}{\Delta x} \quad (1.3)$$

The thermal conductivity equation (1.3), describes the relationship between transported heat per unit of time ( $dQ/dt$  or heat flow  $Q$ ) and the temperature gradient ( $\Delta T/\Delta x$ ) through area  $A$  representing the area through which the heat flows perpendicularly at a steady rate (Figure 1.4) [9].

$$\lambda = K_T = \alpha\rho C_p \quad (1.4)$$

Therefore, thermal conductivity ( $\lambda$ ) is a material-specific property (Figure 1.5) described by the thermal diffusivity ( $\alpha$ ), density of the sample ( $\rho$ ), and specific heat capacity ( $C_p$ ) (Equation 1.4).

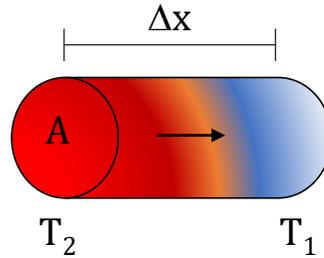

Figure 1.4: Illustration of the relationship between transported heat per unit of time ( $dQ/dt$  or heat flow  $Q$ ) and the temperature gradient ( $\Delta T/\Delta x$ ) through area  $A$  representing the area through which the heat flows perpendicularly at a steady rate.

## 1.6 Low Temperature Specific Heat Properties

The specific heat value is not a constant, particularly at temperatures much lower than room temperature. There are two theories to describe the behavior of the

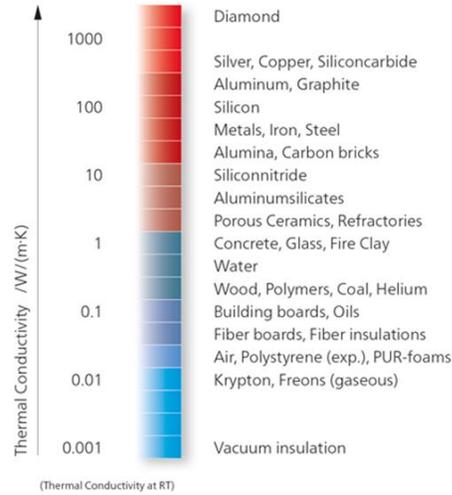

Figure 1.5: An overview of the thermal conductivity for various materials at room temperature.

specific heat of materials over the entire temperature range of interest. The first theory describes the energy contained in the lattice vibrations or phonons (Debye theory) that exist in a solid. For insulators, only the phonon contribution characterizes the specific heat. To determine the phonon specific heat, the internal energy,  $U$ , can be described by the integration of the phonon density of states,  $D(\omega)$ , which describes the fraction of phonons that occupy a particular energy level characterized by its frequency,  $\omega$ , and the statistical distribution function,  $n(\omega)$  for phonons obeying Bose-Einstein statistics (Equation 1.5) [8].

$$U = \frac{h}{2\pi} \int D(\omega)n(\omega)d(\omega) \quad (1.5)$$

By inserting the Debye density of states and distribution function (Bose-Einstein

statistics) into the integral for the internal energy of the phonons, the internal energy is given by Equation 1.6. Here,  $T_D = h\omega_D/k_B$ ,  $x = h\omega/k_B T$ , and  $x_D = h\omega_D/k_B T$  (where  $T_D$  is the Debye temperature and  $\omega_D$  is the maximum phonon frequency representing  $T_D$ ) [8]. Thus,  $x_D = T_D/T$ .

$$U = \frac{9Nk_b T^4}{T_D^3} \int_0^{T_D/T} \frac{x^3}{e^x - 1} dx \quad (1.6)$$

If  $T \gg T_D$ ,  $1 \gg x_D$  and therefore  $e^x - 1 \approx x$ . Thus,  $U$  reduces to Equation 1.7 (Dulong and Petit law) [8].

$$U = 3Nk_b T \quad (1.7)$$

In the limit  $T_D \gg T$ ,  $x_D = \infty$ , and the integral in Equation 1.6 equals  $\pi^4/15$ , and the internal energy expression reduces to Equation 1.8.

$$U = \frac{3\pi^4 Nk_B T^4}{5T_D^3} \quad (1.8)$$

The specific heat is characterized by the change in the internal energy with respect to temperature. Thus, by taking the partial derivative of Equation 1.8, the specific heat from phonon contribution is achieved (Equation 1.9).

$$C_v = \frac{\partial U}{\partial T} = \frac{12\pi^4 Nk_B}{5T_D^3} T^3 = \beta T^3 \quad (1.9)$$

For metals and semiconductors at low temperatures ( $T < 10$  K) the energy contained in the conduction electrons also contributes to the specific heat. To deter-

mine the electronic specific heat, the internal energy,  $U$ , can be described by the integration of the electron density of states,  $D(\varepsilon)$ , which describes the fraction of electrons that occupy a particular energy level characterized by its frequency,  $\varepsilon$ , and the statistical distribution function,  $f(\varepsilon)$  for electrons obeying Fermi-Dirac statistics (Equation 1.10) [8].

$$U = \int D(\varepsilon)f(\varepsilon)d(\varepsilon) \quad (1.10)$$

Similar to above, by inserting the density of states and distribution function (Fermi-Dirac statistics) into the integral, and by taking the partial derivative of the internal energy with respect to temperature, Equation 1.11 can be achieved.

$$C_v = \frac{\partial U}{\partial T} = \frac{\pi^2}{3}k_B^2D(E_f)T = \gamma T \quad (1.11)$$

Combining the phonon contribution and the electronic contribution of the specific heat gives the expression defined by the Einstein-Debye model (Equation 1.12) [8].

$$C_v = \frac{\pi^2}{3}k_B^2D(E_f)T + \frac{12\pi^4Nk_B}{5T_D^3}T^3 = \gamma T + \beta T^3 \quad (1.12)$$

Most metals and small band gap semiconductors obey the Einstein-Debye model and can be confirmed by measuring the heat capacity as a function of temperature and plotting the results as  $C_v/T$  versus  $T^2$  at low temperature, resulting in a linear trend with  $\beta$  representing the slope and  $\gamma$  representing the  $y$ -intercept.

## 1.7 Magnetism

The way in which unpaired valence electrons within an inorganic solid interact describes the array of possibilities of various magnetic effects. If the unpaired electron spins are oriented at random throughout the crystal lattice, the material is considered paramagnetic (Figure 1.6 (a)). The interaction of such unpaired spins could also lead to a cooperative magnetic phenomenon. The spins could align parallel and be described as ferromagnetic (Figure 1.6 (b)), or align antiparallel and be antiferromagnetic (Figure 1.6 (c)). Other magnetic phenomenon such as spin glass behavior is possible (Figure 1.6 (d)). Here, long-range antiferromagnetic ordering throughout the lattice cannot occur as certain regions of spins are paired in a ferromagnetic fashion.

When a material is placed in a magnetic field,  $H$ , the magnetic flux density,  $B$ , (i.e. the density of lines of force in the sample) is related to  $H$  and the magnetic moment,  $M$ , by the permeability,  $\mu_0$  (Equation 1.13) [9, 11].

$$B = \mu_0 H + \mu_0 M \quad (1.13)$$

As shown in Equation 1.13,  $\mu_0$  is the permeability of free space ( $4\pi \times 10^{-7} \text{ H m}^{-1}$ ) with  $\mu_0 H$  as the induction generated by the field alone and  $\mu_0 M$  the induction by the sample. The magnetic susceptibility,  $\chi$ , is the ratio of the magnetic moment to the applied magnetic field (Equation 1.14) [11].

$$\chi = M/H \quad (1.14)$$

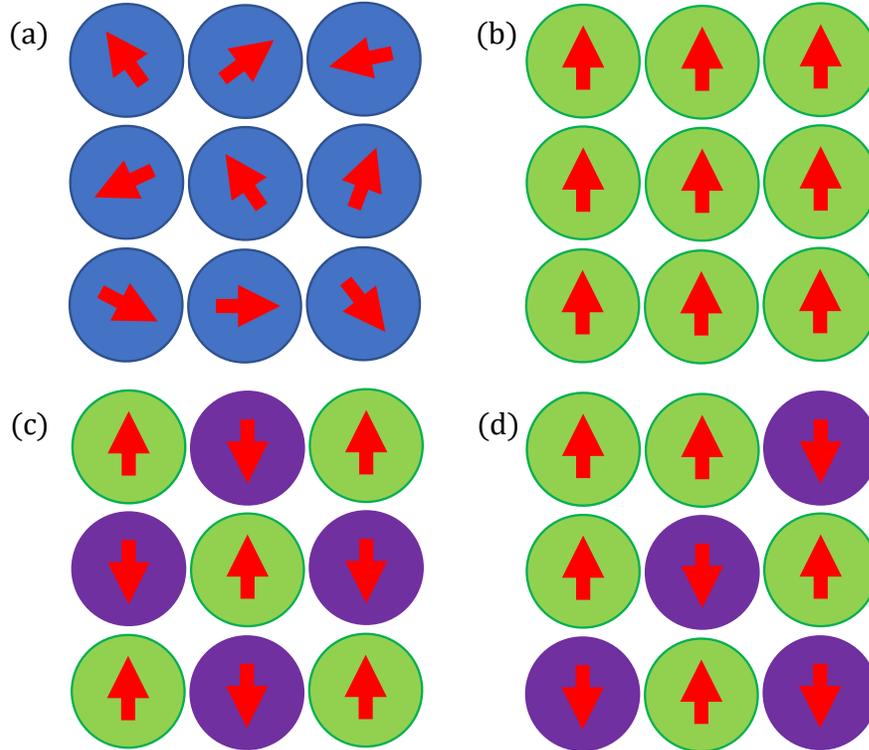

Figure 1.6: Schematic magnetic phenomena in a 2D crystal: (a) paramagnetism, (b) ferromagnetism, (c) antiferromagnetism, and (d) spin-glass.

For diamagnetic materials, the magnetic susceptibility,  $\chi$ , is very small and slightly negative [11]. In the presence of a magnetic field, the small electric field generated by the orbital motion of electrons is modified and therefore alters the orbital motion of electrons slightly to give a magnetic moment that opposes the applied field, leading to a slight repulsion effect (Lenz's law of electromagnetism) [9]. Materials that exhibit paramagnetic behavior reveal a magnetic susceptibility,  $\chi$ ,

that is very small and positive. Type 1 superconductors expel magnetic fields completely meaning  $B=0$  (perfect diamagnetism) and  $H = -M$  and therefore  $\chi = -1$  [9]. Magnetic structures can be distinguished by their magnetic susceptibility dependence on temperature. For ordered magnetic structures such as ferromagnets, above their respective transition temperature, thermal fluctuations with an energy scale  $k_b T$  overwhelm the spin-spin exchange energy,  $J$ , causing the spins to become disordered and therefore in a paramagnetic state [11]. When the overall temperature is lowered below the transition temperature, the spins undergo a phase transition to minimize the total energy. Thus, for ferromagnetic structures, for temperatures below the transition temperature,  $T_c$  (Curie temperature), an increase in the magnetic moment,  $M$ , of the sample with respect to the applied magnetic field,  $H$ , is observed, resulting in an increase in the magnetic susceptibility,  $\chi$  (Figure 1.7). For antiferromagnetic structures, at temperatures lower than the Néel point,  $T_N$ , the electron spins align antiparallel and the magnetic moment,  $M$ , and therefore the magnetic susceptibility,  $\chi$ , both decrease (Figure 1.7). For paramagnetic materials with no transition temperature, spin-spin exchange energy,  $J$ , is weak. Therefore, thermal fluctuations dominate down to low temperature.

Paramagnetic materials will obey the Curie law, which states that the magnetic susceptibility,  $\chi$ , is inversely proportional to temperature,  $T$  (Equation 1.15) [11].

$$\chi = C/T \tag{1.15}$$

For systems with some spontaneous interaction between adjacent spins at low

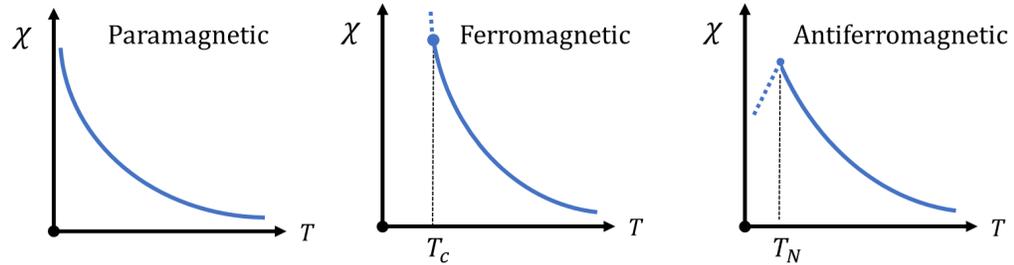

Figure 1.7: Illustrations of disordered and ordered magnetic structures and their magnetic susceptibility dependence on temperature.

temperatures such as ferromagnetic and antiferromagnetic systems, the Curie-Weiss law is obeyed, where  $C$  is the Curie constant and  $\theta$  is the Weiss constant (Equation 1.16) [11].

$$\chi = C/(T - \theta) \quad (1.16)$$

For each of the magnetic structures, plotting the inverse magnetic susceptibility,  $(\chi^{-1})$  versus temperature,  $T$ , within the paramagnetic region will reveal a linear correlation (Figure 1.8). Thus, for paramagnetic materials, the inverse plot extrapolates to 0 K with the Weiss constant,  $\theta$ , equaling 0 K. For ferromagnetic materials,  $0 \text{ K} < \theta$ , and for antiferromagnetic materials,  $\theta < 0 \text{ K}$  (Figure 1.8). Thus, by plotting the inverse magnetic susceptibility,  $\chi^{-1}$  versus temperature,  $T$ , based on the Curie-Weiss law, the Curie constant,  $C$ , represents the slope and the Weiss constant,  $\theta$ , represents the  $y$ -axis.

The relationship between the Curie constant,  $C$ , and the spin quantum number,

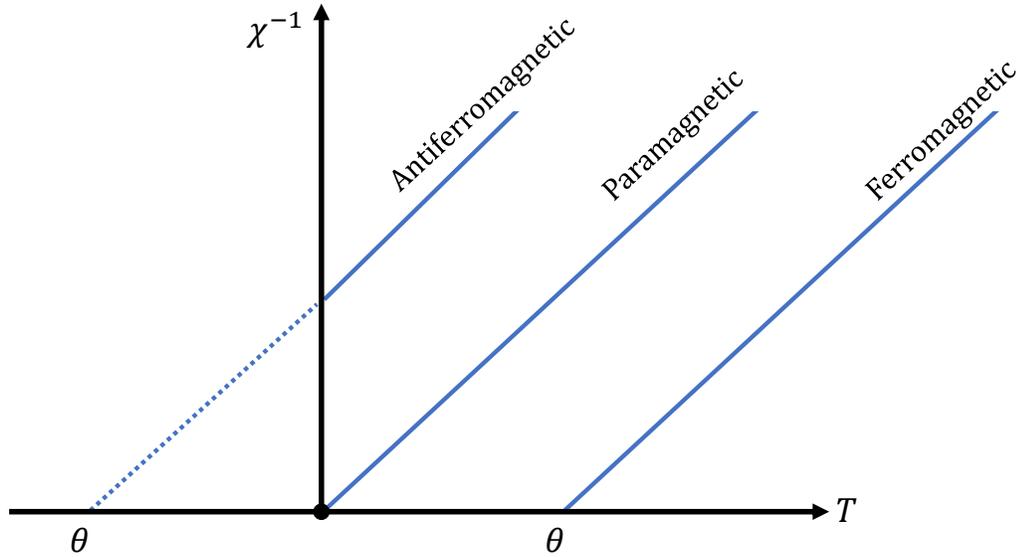

Figure 1.8: Illustration of the reciprocal of magnetic susceptibility,  $\chi^{-1}$ , versus temperature,  $T$ , for paramagnetic materials that may or may not show magnetic ordering at low temperatures.

$S$ , is represented by Equations 1.17 and 1.18, where  $\mu_b$  is the Bohr magneton and the  $g$ -factor is equal to 2 [11].

$$C = \mu_b^2 \mu^2 / 3k_B \quad (1.17)$$

$$\mu = g[S(S + 1)]^{0.5} \quad (1.18)$$

Equation 1.18 can be used to calculate the magnetic moment of a material, where  $S$  is the sum of the spin quantum numbers of the individual unpaired electrons [11]. Thus, by establishing the Curie constant,  $C$ , the effective magnetic

moment,  $\mu$  can be calculated and therefore the spin quantum number can be established. Knowing these variables can corroborate with the presence of magnetic ions within the material of investigation.

## 1.8 Electronic/Thermal Characterization Techniques

### 1.8.1 Introduction

Various electrical and thermal characterization techniques were employed in this dissertation. Here, a brief introduction of such techniques will be addressed.

### 1.8.2 Physical Property Measurement System (PPMS) and Superconducting Quantum Interference Device-Magnetic Property Measurement System (SQUID MPMS)

#### 1.8.2.1 Magnetism

For DC magnetic measurements, the sample is magnetized by a constant magnetic field and the magnetic moment,  $M$ , of the sample is measured, producing a DC magnetization curve  $M(H)$ . The moment is measured most commonly by an induction technique. Inductive measurements are performed by moving the sample relative to a set of copper pickup coils, either by vibration or one-shot extraction, where one measures the voltage induced by the moving magnetic moment

of the sample within the coils. The instrument commonly used to perform such measurements is called a Physical Property Measurement System (PPMS) [12]. A Magnetic Property Measurement System (MPMS) with a Superconducting Quantum Interference Device (SQUID) magnetometer can also be used in which a set of superconducting pickup coils is used to measure the current induced, yielding very high sensitivity to any alteration in the magnetization of the sample [13]. This process is performed over a variable temperature range. In AC magnetic measurements, a small AC drive magnetic field is superimposed on the DC field, resulting in a time-dependent magnetic moment in the sample [14]. The field of the time-dependent moment makes a current in the pickup coils, meaning measurement without sample motion can occur. Spin-glass behavior is usually characterized by AC susceptibility. This process is performed over a variable temperature range. All the magnetic measurements presented in this thesis were collected by Patrick LaBarre and Dr. Arthur Ramirez using a PPMS and SQUID MPMS at UC Santa Cruz.

### 1.8.2.2 Low Temperature Electrical Conductivity

The PPMS can be configured for four-terminal resistance measurements [12]. To perform four-terminal resistance measurements, the sample is mounted on a puck and four leads are attached to the sample. During the measurement the hardware will pass a current through the sample via two leads, using the other two leads to measure the electric potential drop across the sample. The current and the poten-

tial drop can be known to a high degree of accuracy because the input impedance of the voltmeter is very high. This process is performed over a variable temperature range. Most of the low temperature resistivity measurements presented in this dissertation were collected by Patrick LaBarre and Dr. Arthur Ramirez using a PPMS at UC Santa Cruz.

### 1.8.2.3 Low Temperature Heat Capacity

The Heat Capacity of a material can be determined using a Quantum Design PPMS [15]. For this setup, a platform thermometer and a platform heater are attached to the bottom side of the sample platform. Small wires provide the electrical connection between the platforms. The sample is mounted to the platform using a thin layer of grease or epoxy. During a measurement, a known amount of heat is applied at constant power for a fixed time. Once the heater is turned off, an exponential decay of the temperature of the sample versus time is observed, of which the decay pattern can be modeled, and the heat capacity can be extracted. This process is performed over a variable temperature range. All the heat capacity measurements presented in this thesis were collected by Patrick LaBarre and Dr. Arthur Ramirez using a PPMS at UC Santa Cruz.

### 1.8.3 High Temperature Thermal Transport Measurements

The ability of a material to conduct energy in the form of heat can be characterized by determining a material's thermal conductivity. This can be done by measuring the thermal diffusivity of the sample using a Laser Flash instrument [16, 17]. For this method, a Nd:YAG laser is used to provide an infrared radiation pulse normal to the sample. In carrying out a measurement, the lower surface of a plane parallel sample is first heated by a short IR energy pulse (Figure 1.9). The resulting temperature change on the upper surface of the sample is then measured with an IR detector. The higher the sample's thermal diffusivity, the steeper the signal increase. An illustration of the corresponding signal is presented in Figure 1.10.

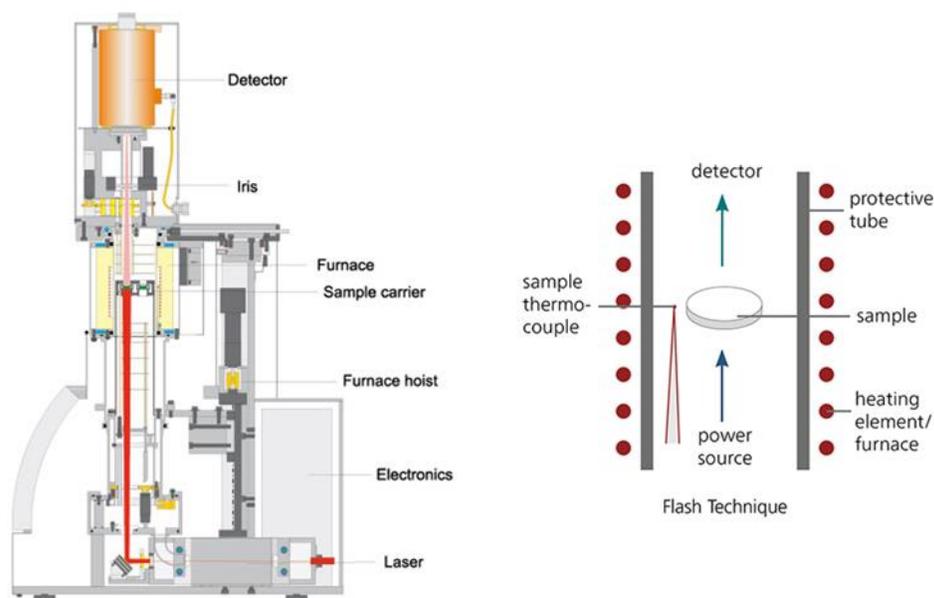

Figure 1.9: Schematic of LFA 457 MicroFlash (1100° C).

By using  $1/2\Delta T_{max}$  which represents  $t_{1/2}$  (Figure 1.10) and sample thickness,  $d$ , the thermal diffusivity,  $\alpha$ , and ultimately the thermal conductivity,  $\lambda$ , can be calculated using Equations 1.4 and 1.19. This process is performed over a variable temperature range. To improve even heating across the sample face, a layer of graphite is applied to the sample prior to measurement.

$$\alpha = 0.1388 \frac{d^2}{t_{1/2}} \quad (1.19)$$

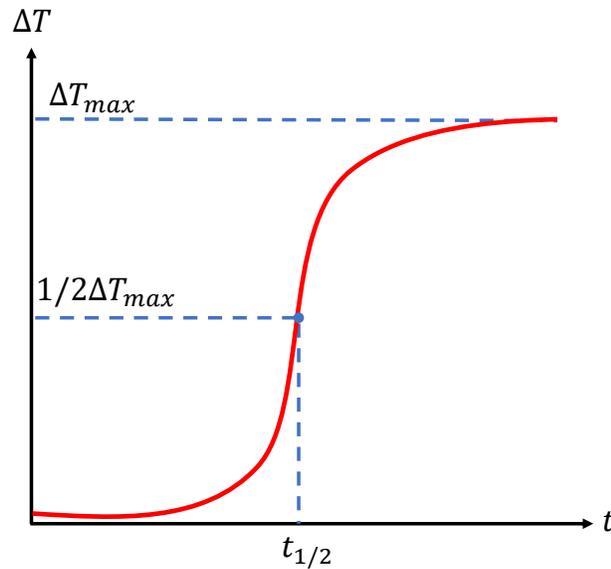

Figure 1.10: Illustration of the change in temperature versus time recorded by the IR detector due to the temperature change on the upper surface of the sample from the applied IR energy pulse.

### 1.8.4 High Temperature Seebeck Electric Resistivity Measurements

High temperature four-probe resistivity measurements were performed using a ZEM-3 instrument [17, 18]. Four leads are attached to a bar as shown in Figure 1.11. The Platinum wire of each of the two R-type thermocouples is used to measure the Seebeck voltage or the voltage drop between the two probes during current flow through the sample to calculate the resistivity of the sample. The resistance of the sample,  $R$ , is determined according to Ohm's law,  $V = IR$ , and  $\rho$  of the sample is determined by incorporating the dimensions  $l$ ,  $w$ , and  $h$  (Equation 1.20) [17].

$$\rho = Rwh/l \quad (1.20)$$

The current and the potential drop can be known to a high degree of accuracy for the four-probe method because the input impedance of the voltmeter is very high.

## 1.9 Electron Paramagnetic Resonance Spectroscopy

Electron paramagnetic resonance (EPR) spectroscopy is used for studying paramagnetic compounds with unpaired electrons. The basic concept of EPR is analogous to nuclear magnetic resonance (NMR), the difference being excitation of the electron spins instead of the spins of atomic nuclei. The intrinsic angular momentum of an electron generates a magnetic dipole moment,  $\mu$ . For a single unpaired

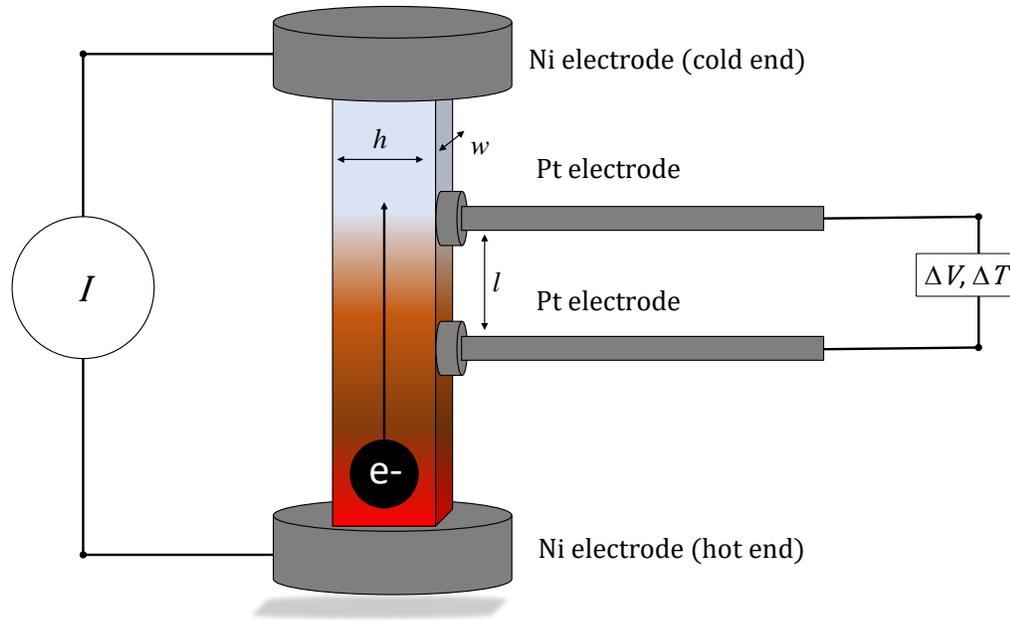

Figure 1.11: Illustration of the measurement of four-probe resistivity and Seebeck coefficient in a sintered bar sample.

electron, under the application of a magnetic field with strength  $B$ , the potential energy developed from the interaction of the magnetic dipole moment and the applied magnetic field can be represented by Equation 1.21 where  $\theta$  represents the angle between the magnetic dipole vector and the applied field vector,  $m_s = \pm\frac{1}{2}$ , and  $g_e$  is the Landé  $g$ -factor [19, 20].

$$U = m_s g_e \mu_B B \cos \theta \quad (1.21)$$

Thus, the potential energy is dependent on the moments vector direction relative to the applied field. If the electron's magnetic moment aligns itself exactly

parallel to the field, a minimum or maximum potential energy can be achieved, depending on the moment vector direction relative to the field. The difference between  $U_{min}$  and  $U_{max}$  is expressed by Equation 1.22 (Zeeman energy splitting) [19,20].

$$\Delta E = g_e \mu_B B \cos \theta \quad (1.22)$$

Equation 1.22 therefore states that the splitting of  $U_{min}$  and  $U_{max}$  is directly proportional to the magnetic field's strength,  $B$ . An unpaired electron can transition between the maximum/minimum energy levels by either absorbing or emitting a photon of energy,  $h\nu$ . Thus, Equation 1.23 is established [19,20].

$$h\nu = g_e \mu_B B \cos \theta \quad (1.23)$$

Equation 1.23 suggests a large variety of frequency and magnetic field value combinations. EPR measurements, however, are typically conducted with magnetic fields around 0.3-0.4 Tesla and with microwaves in the 8-10 GHz region [20]. EPR measurements are usually conducted where the frequency is kept fixed with the applied magnetic field as a variable. Various information can be obtained from EPR spectroscopy, such as the identity of elements and what oxidation state is present [21]. The Zeeman energy splitting due to an applied magnetic field is related to the  $g$ -factor, which for systems that have relatively insignificant spin-orbit coupling (SOC) energies,  $g=2.0023$  [19]. With the incorporation of large spin-orbit coupling, however, the Zeeman energy splitting results in a  $g$ -factor value

that deviates from 2.002, of which the difference is associated to the SOC. There are various perturbation theory equations that relate the observed  $g$  values to a spin-orbit coupling constant, though all are for  $3d$  ions where the SOC can be treated as a perturbation, compared to the ligand-field effects [19, 22].

## 1.10 Computational Methods

Computational methods can provide useful information about the electronic properties of a material. The open-source package ABINIT was used to perform electronic calculations for Chapter 7 [23]. ABINIT utilizes density functional theory; implementing a plane wave basis set and pseudopotentials to compute the electronic density and derived properties of a particular system. Details of the exact model can be found in Chapter 7. All calculations were performed by Dr. Warren Pickett's research group at University of California, Davis.

## Chapter 2: Enigmatic States of Matter

### 2.1 Abstract

Transition-metal oxides with partially filled  $4d$  and  $5d$  shells exhibit an intricate interplay of crystal field, spin-orbit coupling (SOC), and electronic correlations. For  $3d$  compounds, the atomic interactions, crystal field, and electronic correlations can energetically compete, with the SOC remaining small. In heavy  $5d$  transition metal oxides, however, SOC is significant, and all energy scales are comparable. Small changes in such effects can drastically influence the electronic properties, resulting in a variety of novel forms of quantum matter (Figure 2.1) [24, 25]. This chapter will provide a brief introduction of such effects in addition to highly sought-after enigmatic states of matter: the quantum spin liquid and the topological insulator.

### 2.2 $d$ -Electron Effects

For transition metal complexes, the valence  $d$ -electrons can influence the coordination environment of the metal atom which can therefore affect electronic properties. Crystal field theory (CFT) is adequate to describe the effects that occur [26]. For a metal-ligand environment, all five valence  $d$ -orbitals on the transition metal are not degenerate. For example, in an octahedral environment, valence  $d$ -orbitals

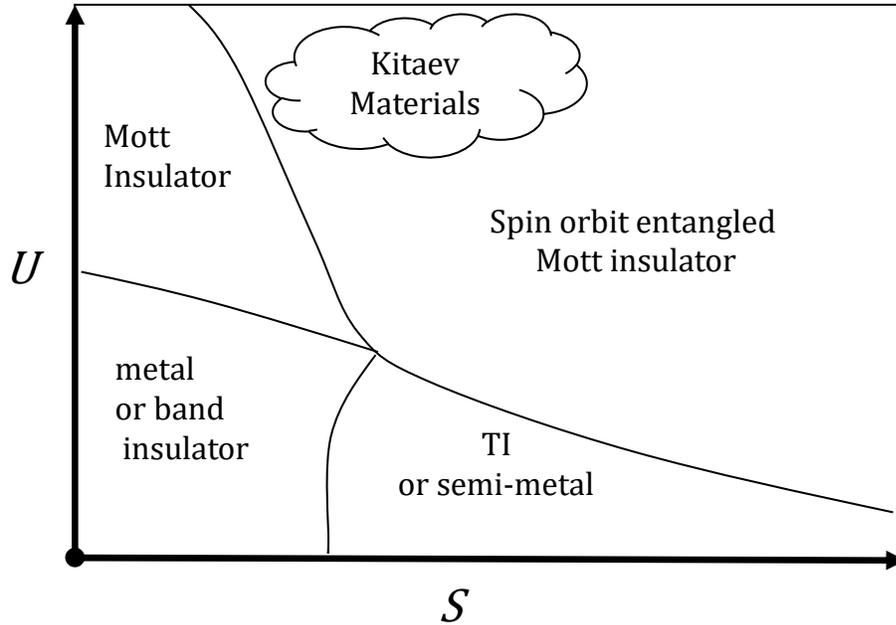

Figure 2.1: Illustration of how the electronic property of a material changes when varying the magnitudes of spin-orbit coupling,  $S$ , and electronic correlations,  $U$ . Figure adapted from review [25].

split into two groups; the  $t_{2g}$  group (3 degenerate  $d$ -orbitals) are lower in energy than the  $e_g$  group (2 degenerate  $d$ -orbitals) (Figure 2.3). If the difference in energy between the  $e_g$  and  $t_{2g}$  states,  $\Delta O_h$ , is less than the pairing energy,  $P$ , of two electrons occupying a given  $t_{2g}$  orbital, Hund's rule is obeyed, forming a high-spin state. If, however,  $\Delta O_h > P$ , the  $t_{2g}$  states fill first, forming a low-spin state. The magnitude of  $\Delta O_h$ , in part, depends on the transition metal: generally  $\Delta O_h(5d) > \Delta O_h(4d) > \Delta O_h(3d)$  [26].

## 2.3 Electron Correlation

The band model (discussed in Chapter 1) is often inadequate for describing the properties of metal oxides as the bands of such compounds are typically too narrow for the effects of electron-electron interaction to be ignored [26]. For the simple band model, it is assumed that the repulsion between electrons can be represented with an independent electron orbital wavefunction to describe the average effective potentials of the electrons. For simple intermetallic systems, this approach is generally acceptable as the highly mobile electrons described by the wide bands possess good screening properties. The Hubbard  $U_H$  approximation is particularly useful to circumvent this inaccurate description for metal oxides [26]. Here, the repulsion between electrons is neglected, except when they are on the same atom. For a given metal-oxide system, unpaired electrons within the  $d$ -orbitals can effectively "hop" between transition metal sites. The energy input required to translate between metal sites along with the energy of the now extra electron repulsion describes the Hubbard  $U_H$  energy. If  $U_H > E_g$ , a Mott insulator will exist. If  $U_H < E_g$ , a semiconductor/metallic system will exist [26].

## 2.4 Spin-Orbit Coupling

Spin-orbit coupling is the interaction of an electron's intrinsic angular momentum, or spin, with the orbital motion of the electrons through space [25]. This spin-orbit coupling can be better understood by examining the effect in terms of the motion of the nucleus of charge  $Ze$  ( $Z$  is the atomic number) with respect to the electron's

position. Thus, with respect to the electrons viewpoint, the nucleus circulates about the electron with the same angular momentum,  $l$ , as the electron orbiting the nucleus (Figure 2.2). This relative motion creates a current (Equation 2.1) and such a current generates a magnetic field at its centre (Equation 2.2) [27].

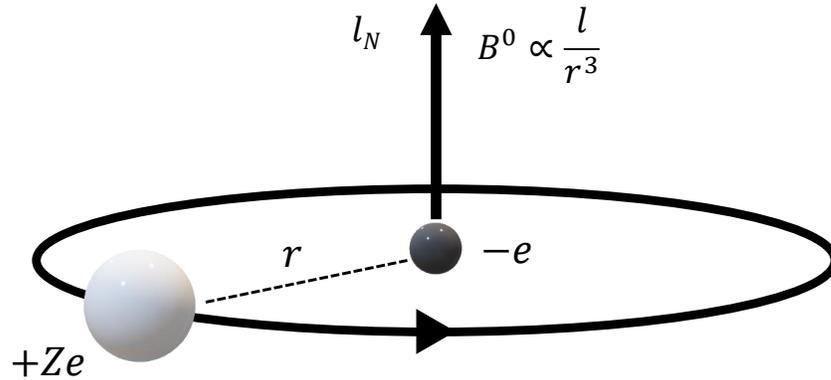

Figure 2.2: Illustration of the magnetic field at an electron produced by the relative motion of the nucleus.

$$I = \frac{Ze|l|}{2\pi m_e r^2} \quad (2.1)$$

$$B^0 = \frac{\mu_0 I}{2r} = \frac{Ze\mu_0}{4\pi m_e r^3} |l| \quad (2.2)$$

The intrinsic angular momentum, or spin, of the electron also has an associated magnetic moment (Equation 2.3) where  $g_e$  is the spin  $g$ -factor ( $g_e \approx 2$ ) [27]. The electron spin interacts with the field  $B^0$  resulting in potential energy expressed in

Equation 2.4 [27].

$$m^s = -g_e \frac{e}{2m_e} s \quad (2.3)$$

$$E_{so} = -m^s B^0 = \frac{\mu_0 Z e^2 g_e}{8\pi m_e^2 r^3} s \cdot l = \xi(r) s \cdot l \quad (2.4)$$

Thus the spin-orbit interaction energy,  $E_{so}$  scales with the atomic number,  $Z$ . Atoms with a high atomic number therefore have a strong spin-orbit force and electrons travelling through materials composed of such atoms therefore feel a strong spin- and momentum-dependent force that resembles a magnetic field.

Of recent interest for exotic states such as topological insulators (described in Chapter 3.7) are  $4d/5d$  metal oxide systems where SOC is large enough to influence the electronic band structure. Iridates are the most widely studied with Iridium frequently in a  $4+$  oxidation ( $5d^5$ ) state [25, 28, 29]. Certain frustrated systems with such  $5d^5$  ground states have been predicted to possess anisotropic exchange interactions, a key ingredient of the Kitaev model of a quantum spin liquid (described in Chapter 2.6) [30].

The valence  $d$ -orbital energy level scheme of such  $d^5$  ionic systems is illustrated in Figure 2.3. With the crystal field splitting of the valence  $d$ -orbital levels, for a  $5d^5$  ionic system, the five electrons occupy the  $t_{2g}$  orbitals. The SOC acts within the  $t_{2g}$  manifold as  $-\lambda \mathbf{L} \cdot \mathbf{S}$ , where  $\mathbf{L}$  is an effective  $l = 1$  angular momentum [31],  $\mathbf{S}$ , is the spin, and  $\lambda$  is the magnitude of the SOC. Using the rules of addition of angular momenta, SOC will split the  $t_{2g}$  levels into an effective  $j = 3/2$  quartet and an effective  $j = 1/2$  doublet with an energy difference of  $3\lambda/2$ , as shown in Figure 2.3.

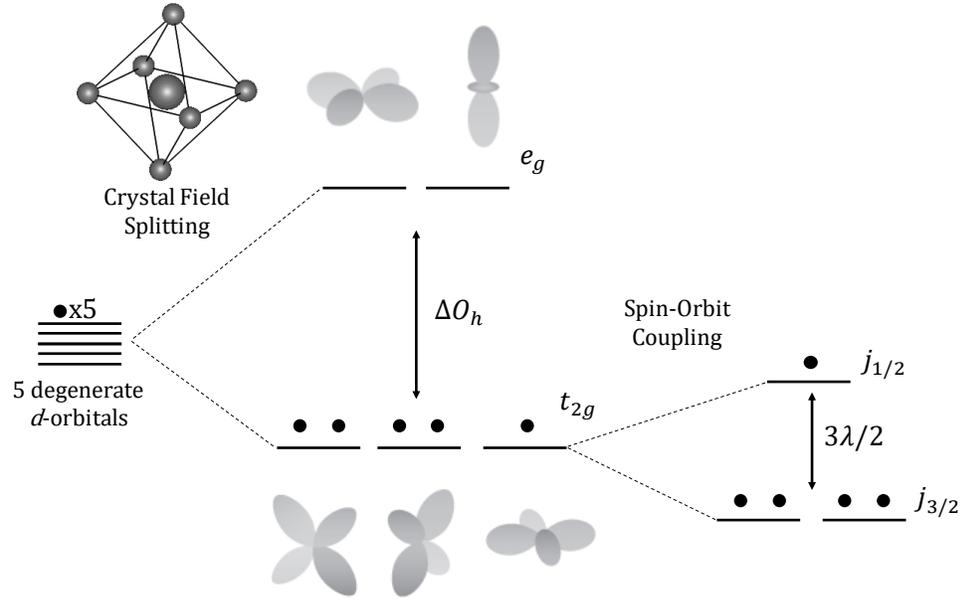

Figure 2.3: Formation of spin-orbit entangled  $j = 1/2$  moments for ions in a  $d^5$  electronic configuration.

Strong spin-orbit coupling then results in a system with a fully filled  $j = 3/2$  band and a half-filled  $j = 1/2$  band for a  $d^5$  system (Figure 2.3) [25]. The magnitude of the SOC varies amongst the  $4d$  and  $5d$  transition metals. For example, the SOC of iridium and osmium is 540 meV and 480 meV, respectively [32]. For a small band gap semiconductor or metal, the  $t_{2g}$  splitting induced by SOC plays a significant role in the gap energy and electrical properties.

## 2.5 Anisotropic Nature of the Honeycomb Lattice

The framework of the honeycomb lattice enables anisotropic behavior unique to other systems [33]. The distances and angles between the three nearest edge-shared octahedral neighbors are not equivalent, resulting in orthogonal anisotropy between the three nearest-neighbor bonds. In addition, large spin-orbit coupling contributes to anisotropic magnetic interactions between the three nearest neighbors [34]. Such characteristics give rise to strong magnetic frustration and therefore an ideal playground to study various exotic states such as quantum spin liquid (QSL) behavior.

## 2.6 Quantum Spin Liquids and the Kitaev Model

### 2.6.1 Introduction

A quantum spin liquid (QSL) represents a new state of matter. Unlike conventional magnetic states, such as the ferromagnetic or the antiferromagnetic states (see Chapter 1), a QSL never enters into a long-range ordered phase with a static arrangement of spins, even at absolute zero temperature [35]. For ferromagnets, above the Curie temperature  $T_c$ , thermal fluctuations with an energy scale  $k_b T$  overwhelm the spin-spin exchange energy,  $J$ . When the overall temperature of a ferromagnetic system is lowered below  $T_c$ , the spins undergo a phase transition to minimize the total energy. The ground state of the ferromagnetic Heisenberg model is an eigenstate with parallel spins. The ground state of the antiferro-

magnetic Heisenberg model, however, is not a true eigenstate with antiparallel spins and can only be a linearly superposed singlet state representing the ground state [27]. This understanding is what led to the initial discussion of the existence of a QSL state. In 1973, Anderson proposed that in an edge-sharing triangular lattice, the three spins at the corners cannot be made mutually antiparallel, therefore geometrical frustration could prevent spins from undergoing magnetic long-range ordering [36]. Anderson postulated that the spins throughout a triangular lattice would form local singlet pairs and the spins would constantly alter and rearrange the pairings, resulting in a “liquid-like” state of spins [36]. Nevertheless, nearly all known frustrated lattice systems form a magnetic ordered state at some temperature above 0K [37]. The discovery of the cuprate superconductors led to the investigation of the spin- $\frac{1}{2}$   $\text{Cu}^{2+}$  ions arranged in  $\text{La}_2\text{CuO}_4$  square lattice as a potential QSL candidate [38]. However,  $\text{La}_2\text{CuO}_4$  was later confirmed to possess a Néel ordered state [39, 40].

### 2.6.2 Kitaev Model

A QSL state of matter has recently been demonstrated by an exactly solvable model on a 2D honeycomb lattice by Alexi Kitaev [41]. By introducing Majorana operators, Kitaev showed that the ground state of the associated Hamiltonian is a quantum spin liquid [41]. The exploration of physical proof of this model began with honeycomb layered  $\text{A}_2\text{MO}_3$  (A = group 1 cation and M =  $4d/5d$  transition metal). More specifically, iridate  $\text{A}_2\text{IrO}_3$  were first proposed as a candidate non-

eycomb Kitaev model [34, 42].

Discovering a physical realization of the Kitaev model has been proven to be a challenge. All currently known  $A_2MO_3$  honeycomb layered systems, with the potential exception of  $Li_{2.15}Os_{0.85}O_3$ , have been shown to not possess QSL behavior [43]. There are currently four known systems that show prominent characteristics of the Kitaev model: honeycomb layered  $Li_{2.15}Os_{0.85}O_3$ ,  $Cu_2IrO_3$ ,  $\alpha$ - $RuCl_3$ , and Herbertsmithite  $ZnCu_3(OH)_6Cl_2$  [43–46].

For  $Li_{2.15}Os_{0.85}O_3$ , a large van Vleck susceptibility, and an effective moment of  $0.85 \mu_B$  (much lower than expected from 70%  $Os(+5)$ ), and a narrow transport band gap of  $\Delta = 243 \pm 23 \text{ meV}$  is observed [43]. No evidence of long range magnetic ordering is found above 0.10 K, however, a spin glass-like peak in ac-susceptibility is observed at 0.5 K. The specific heat displays an impurity spin contribution in addition to a power law  $\propto T^{(0.63 \pm 0.06)}$ . The magnetic susceptibility and specific heat are not easily understood using a local moment picture, which suggests that the valence electrons are close to itineracy and that spin orbit coupling of osmium is playing an important role in the collective electronic behavior of the  $Li_{2.15}Os_{0.85}O_3$  honeycomb system.

Unlike  $Na_2IrO_3$ , which shows long range magnetic ordering  $T_N = 15 \text{ K}$  [47],  $Cu_2IrO_3$ , remains disordered until 2.7 K with zero field cooling [45]. The order, however, disappears in a weak magnetic field, therefore suggesting short-range magnetic ordering [45]. In addition, unlike  $Na_2IrO_3$  which shows a clear peak at the antiferromagnetic transition  $T_N = 15 \text{ K}$  in the heat capacity measurements, such a peak is absent from the transition in  $Cu_2IrO_3$  at 2.7 K. The effective magnetic

moment of  $1.93 \mu_B$  and a Curie Weiss constant of -110 K suggests, however, that the valence electrons are not in itinerate form.

When the magnetic spins throughout a lattice enter an ordered state, the low-energy excited states are defined as spin waves and the quantum of excitation is called a magnon [48]. For exotic systems in which the spins fractionalize, the allowed energies form a spinon continuum, unique from magnon dispersion. Spinons, therefore, contribute to bulk properties in ways that are distinct from magnons [49]. One of the defining properties of QSL's is that they possess a high degree of quantum entanglement, and support spinons which carry fractional quantum numbers [50]. To obtain information about such fractionalized spinon excitations requires a momentum and energy resolved technique such as inelastic neutron scattering. With inelastic neutron scattering, the magnetic neutron scattering cross section is proportional to the dynamic structure factor  $S(Q, \omega)$ , where  $Q$  and  $\omega$  are the momentum and energy transferred to the sample, respectively. Thus the scattered neutron intensity is a measure of  $S(Q, \omega)$  in reciprocal space of the spin-spin correlation function [44, 46, 50–52].

Plots of  $S(Q, \omega)$  for  $\alpha$ - $\text{RuCl}_3$  and Herbertsmithite  $\text{ZnCu}_3(\text{OH})_6\text{Cl}_2$  show scattered intensity is diffuse and covers a large fraction of the Brillouin zone, even at temperatures significantly below  $J/k_B$ , where  $J$  is the spin-spin exchange energy [44, 46]. As a comparison, the square-lattice  $\text{La}_2\text{CuO}_4$  develops antiferromagnetic correlations for  $T < 0.5 J/k_B$  [39]. Though  $\alpha$ - $\text{RuCl}_3$  shows a magnetic ordering transition at  $T_N = 7$  K, resulting inelastic neutron scattering supports scattering from the Majorana excitations, a defining characteristic of the Kitaev

model [44]. For Herbertsmithite  $\text{ZnCu}_3(\text{OH})_6\text{Cl}_2$  no magnetic ordering occurs down to temperatures near 0 K, a defining property of a QSL system [49, 53].

## 2.7 Quantum Computation and QSL

Quantum computation is the most attractive potential application of a QSL. Quantum computers (QC's) are different from binary digital electronic computers based on transistors, as quantum bits (qubits) rely on superposition and entanglement of states [54]. A major issue of current QC's is quantum decoherence, causing the inability to store information for extended periods of time due to local perturbations from the surrounding environment [54]. One of the defining properties of QSL's is that they possess a high degree of quantum entanglement and are topologically invariant [41, 50]. If a physical system has topological degrees of freedom, then information contained in those degrees of freedom would be automatically protected against errors caused by local interactions with the environment [55]. The archetypal example of a topological phase with strong electron interaction is the QSL [56]. Despite intensive experimental efforts on numerous candidate materials for the potential realization of a QSL, only a select few are proposed to have QSL behavior. It is therefore imperative to discover new QSL systems for fault-tolerant quantum computation to become a reality.

## 2.8 Quantum Hall Effect and Topological Insulators

### 2.8.1 Introduction

The quantum hall state (QHS) is an example of a quantum state that is topologically invariant [57]. Topology deals with objects that are robust against small local perturbations and is a branch of mathematics concerned with those properties of geometric configurations that are unaltered by elastic deformation [55]. Topological insulators (TI) are analogous to the quantum Hall state in that they exhibit topological order. Quantum information contained in such topological degrees of freedom would be automatically protected against errors caused by local interactions with the environment [55]. Thus, such materials may be useful for applications like spintronics and quantum computation [57].

### 2.8.2 Quantum Hall Effect

For a 2D  $xy$  insulating surface, the quantum hall effect can be achieved when a strong magnetic field is applied in the  $z$ -direction [58]. The applied magnetic field causes the electrons to experience a perpendicular Lorentz force, which causes their motion to curve into  $xy$  circular orbits (Figure 2.4 (a)). The quantization of the electrons circular orbits with orbital frequency creates quantized Landau levels. Electrons near the  $xy$  edges, however, undergo a different kind of motion, and lead to electronic states that propagate along the edge and do not have quantized energies, meaning these states can conduct (Figure 2.4 (a,b)) [57, 58].

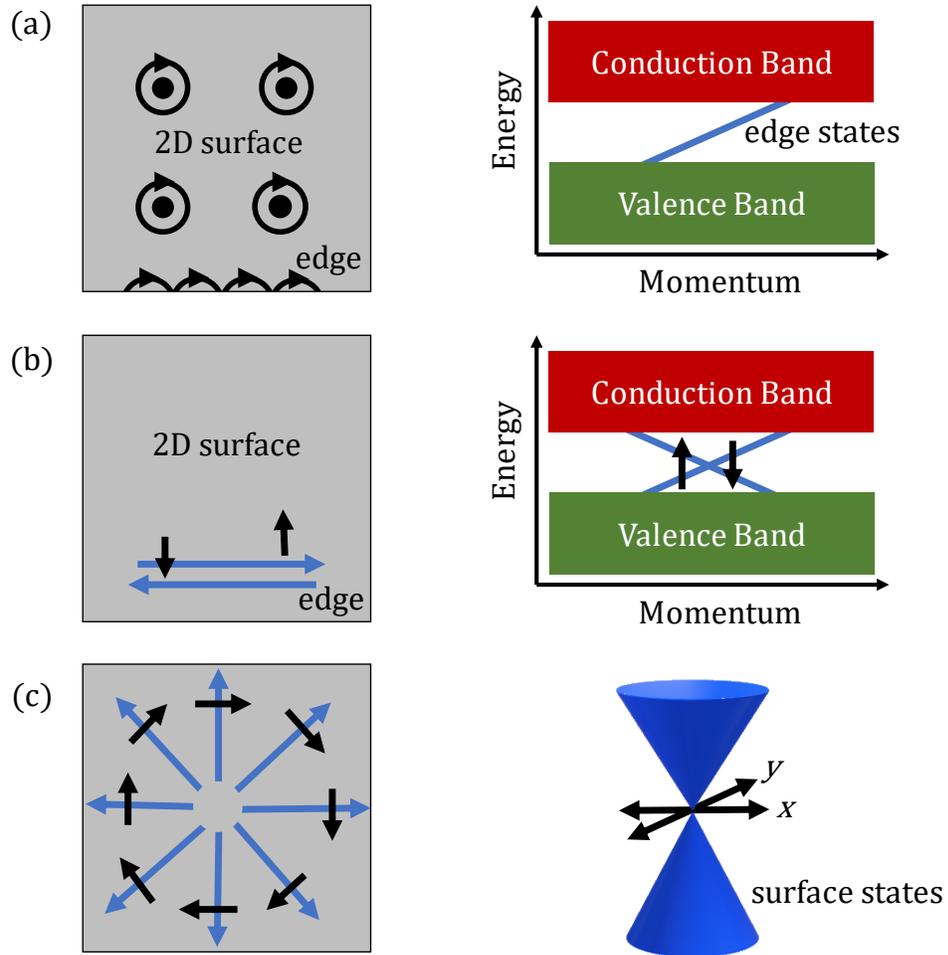

Figure 2.4: In the quantum Hall effect, the applied magnetic field in the  $z$ -direction causes the electrons to experience a perpendicular Lorentz force, which causes their motion to curve into  $xy$  circular orbits (a). For electrons on the edge states, there are two directions of propagation with opposite spins (b). Electrons on the surface of a 3D topological insulator do resemble the edge states of a 2D topological insulator where the spin direction is locked to the direction of propagation. The surface bands intersect at a “Dirac point” and form a Dirac cone in reciprocal space (c).

### 2.8.3 Topological Insulator

The topological insulator is closely related to the QHS except for the required large magnetic field. The role of the magnetic field is played by spin-orbit coupling and is commonly known as the quantum *spin* Hall state [57]. With the combination of strong spin-orbit interactions and time-reversal symmetry, the observed properties are unlike any other known electronic systems. For electrons on the edge states, there are two directions of propagation with opposite spins (Figure 2.4). Upon a time reversal operation, the direction of propagation is reversed and (because of time-reversal symmetry) the spin direction is also reversed, interchanging the two counter-propagating modes [55, 57–59]. This leads to what is known as dissipationless transport: immune to any back-scattering from defects or impurities. The surface states of a 3D topological insulator do resemble the edge states of a 2D topological insulator, in that the direction of electron motion along the surface of a 3D topological insulator is determined by the spin direction where the spin direction is locked to the direction of propagation (Figure 2.4 (c)) [59]. The surface bands intersect at a Dirac point and form a Dirac cone in reciprocal space (Figure 2.4 (c)).

The first experimental proof of the 2D TI was made by placing a thin layer of mercury telluride (HgTe) between layers of mercury cadmium telluride ( $\text{Hg}_x\text{Cd}_{1-x}\text{Te}$ ) [59, 60]. The first 3D TI was the semiconducting alloy bismuth antimonide ( $\text{Bi}_x\text{Sb}_{1-x}$ ) [61]. Measurements of electrical transport are ideal for probing the 2D quantum spin Hall effect are more problematic for 3D topological insulators, as even for a

bulk insulator, small bulk conductivity still exists. It is therefore hard to separate the bulk and surface contributions to the current. Angle-resolved photo-emission spectroscopy (ARPES) couples only to the surface and is therefore the preferred route when establishing the existence of a 3D quantum spin Hall state [59, 61]. By analyzing the energy, momentum and spin of the electrons emitted from the sample (photoelectric effect), the electronic structure of the surface states can be directly measured.

The quantum Hall Effect of a two-dimensional honeycomb net model was first theoretically investigated by F.D.M. Haldane [62]. From the model presented, a nonzero quantization of the Hall conductance could be achieved in the absence of an external magnetic field. The band structure of 2D honeycomb graphene reveals the difference in energy of the conduction and valence band becoming zero at two distinct points in the Brillouin zone. Near these points, the electronic dispersion resembles the linear dispersion of massless relativistic particles, which can be described by the Dirac equation. From this, the quantum spin Hall Effect was theoretically predicted for the honeycomb layered  $\text{Na}_2\text{IrO}_3$  with large spin-orbit interaction and the electron correlation playing crucial roles [63, 64]. The interest toward fundamental investigations of heavy metal honeycomb layered metal oxide systems for possible TI based applications has since grown.

## 2.9 Conclusion

It is well established that the interplay between crystal field, spin-orbit coupling, and electron correlation energies within various transition metal oxide and intermetallic systems generates a wide variety of novel forms of quantum matter. Only a select few of such novel quantum states were discussed in this chapter. Other notable states are Weyl and Dirac semi-metals [65]. The theorized topological superconductor is projected to support topologically protected room temperature superconductivity [66]. It is therefore crucial to synthesize new heavy metal oxide and intermetallic systems where large spin-orbit coupling will play an influential role in the electronic properties.

## Chapter 3: Introduction to Thermoelectric Materials and Applications

### 3.1 Introduction

Over the past few decades, a lot of attention has been focused on alternative energy sources to relieve our dependence on fossil fuels and to reduce greenhouse gas emissions [67]. Approximately 70% of energy consumed is ultimately wasted in the form of heat [67]. Thermoelectric generators (TEGs) are power-generation devices that are designed to convert waste heat into electrical energy. They can also be used as solid-state refrigeration devices, eliminating the need for CFC chemicals. The advantages of using TEGs are that they can collect waste heat covering a very wide temperature range without any vibration, noise, or gas emissions, and with no refueling or maintenance requirements [68–70]. Unfortunately, “good” TE materials possess 10-20% energy conversion efficiency [67, 68, 71]. Thus, there has been considerable interest in TEGs, driven by the desire for more efficient materials for electronic power generation and refrigeration [67, 68, 70, 72].

There are a wide array of technological applications that use thermoelectric (TE) materials. For example, TE applications are currently in use by the automotive industry to develop electrical power from waste engine heat from the radiator and exhaust systems for use in next-generation vehicles [67, 68]. In addi-

tion, TE refrigeration applications include seat coolers for comfort and electronic component cooling [67, 73]. Several deep space NASA missions have used TE materials; NASA's Voyager, Cassini, and Mars Rover missions have used radioisotope thermoelectric generators [74–76].

### 3.2 Thermoelectric Circuit

A thermoelectric circuit is composed of  $p$ -type and  $n$ -type semiconductors configured in parallel as a thermoelectric generator (Figure 3.2). For thermoelectric power generation to occur, the hot ends of the  $n$ -type and  $p$ -type material must be electrically connected with a load connected across the cold ends. By applying a temperature gradient across the junctions, a voltage gradient develops that is proportional to the temperature gradient. The resulting voltage produced by the Seebeck effect will cause current to flow through the load, generating electrical power (Figure 3.1). Thus, the electrical power produced is the product of the electrical current and voltage across the load. By applying an external electric potential across the load, heat can be forced to flow from one end to the other via heat carrying charges and enable what is known as Peltier cooling effect (Figure 3.1).

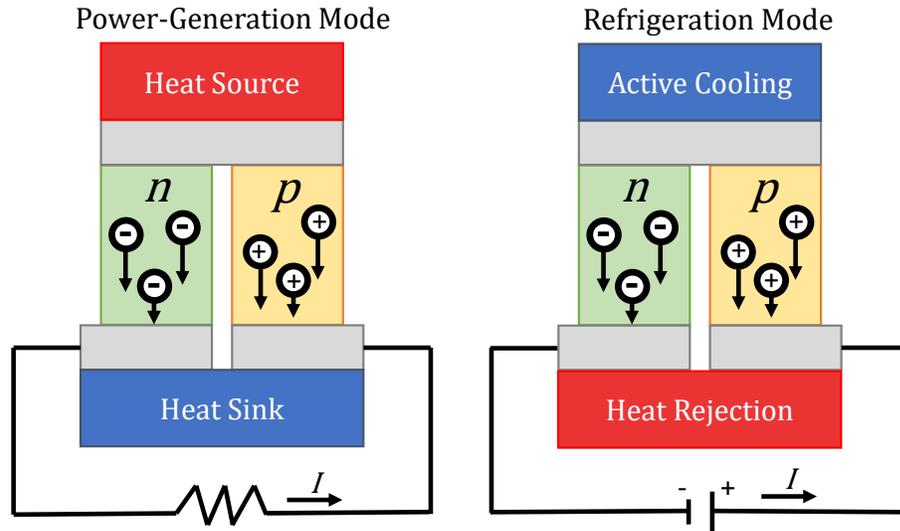

Figure 3.1: A thermoelectric cooling/heating device is composed of a series of connected semiconductor junctions ( $n$ - and  $p$ -type).

### 3.3 Quantifying Thermoelectric Performance

The thermoelectric performance of a material is characterized by the thermoelectric figure of merit, expressed in Equation 3.1, where  $S$  is the Seebeck coefficient,  $\sigma$  is the electrical conductivity,  $T$  is the effective temperature, and  $K$  is the summation of the lattice and electronic components of the total thermal conductivity ( $K_L + K_e$ ) [67, 68, 70, 72].

$$ZT = \frac{\sigma S^2 T}{K} \quad (3.1)$$

The efficiency of a power generation device,  $\eta$ , is proportional to  $\sqrt{(1 + Z\bar{T})}$

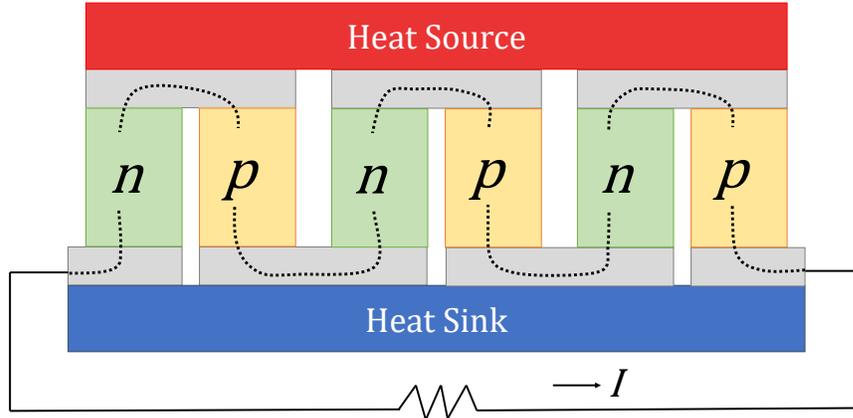

Figure 3.2: A thermoelectric cooling/heating device composed of a series of connected semiconductor junctions ( $n$ - and  $p$ -type).

and is expressed in Equation 3.2, where  $\bar{T}$  is the average temperature of the hot-end temperature ( $T_h$ ) and the cold-end temperature ( $T_c$ ) [71].

$$\eta = \frac{T_h - T_c}{T_h} \frac{\sqrt{(1 + Z\bar{T})} - 1}{\sqrt{(1 + Z\bar{T})} - \frac{T_c}{T_h}} \quad (3.2)$$

From this, the efficiency will approach the Carnot efficiency when  $ZT$  approaches infinity. For  $ZT = 1$ , the efficiency  $\eta$  is approximately 10% [67].

Considered to be “good” thermoelectric materials have a  $ZT \geq 1$  [67,68]. Well established low temperature (300 – 400 K) thermoelectric materials with  $ZT \geq 1$  are  $\text{Bi}_2\text{Te}_3$  and  $\text{Bi}_2\text{Te}_{3-x}\text{Se}_x$  alloys [77]. For operating temperatures  $\sim 900$  K, SnSe has a recorded  $ZT$  of  $\sim 2.7$  [78]. Figure 3.3 shows the relation between  $T$ ,  $\eta$ , and  $\Delta T$  of materials with different  $ZT$  values (inset) and  $ZT$  as a function of temperature for typical high-efficiency thermoelectric materials [67].

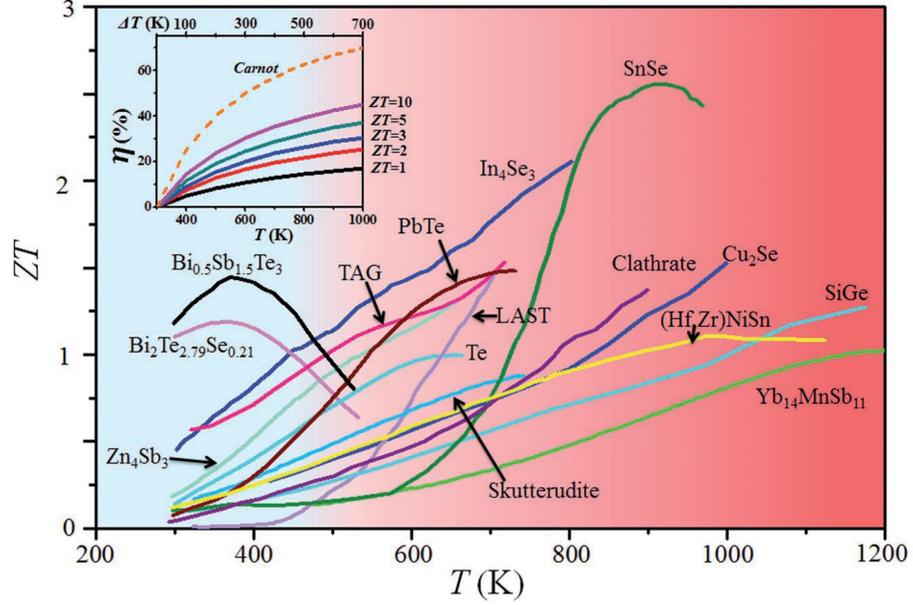

Figure 3.3: Illustration of the relation between  $T$ ,  $\eta$ , and  $\Delta T$  of materials with different  $ZT$  values (inset) and  $ZT$  as a function of temperature for typical high-efficiency thermoelectric materials (figure adapted from Yang et al [67]).

The Seebeck coefficient,  $S$ , is an intrinsic property representing the ratio of the voltage developed to the temperature gradient ( $\Delta V/\Delta T$ ) across a material. An increase in thermoelectric performance corresponds to an increase in the  $ZT$  value. Since  $S=\Delta V/\Delta T$ , the ability to maintain a potential gradient will in general diminish with the increase in the majority  $e^-/h^+$  mobility and carrier concentration [67]. Thus, as illustrated in Figure 3.4, the conductivity,  $\sigma$ , will increase with an increase in charge carrier concentration, however, the magnitude of the Seebeck coefficient,  $S$  will decrease. Thus,  $S$ ,  $\sigma$ , and  $k_e$  directly relate with the carrier

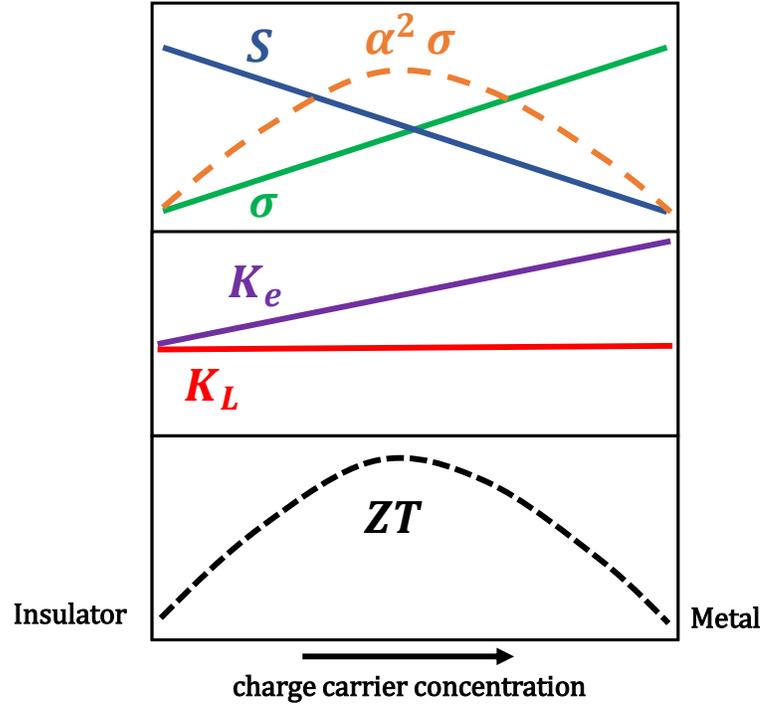

Figure 3.4: Illustration of how the Seebeck coefficient,  $S$ , electrical conductivity  $\sigma$ , lattice,  $K_L$ , and electronic,  $K_e$ , portions of the thermal conductivity change with charge carrier concentration.

concentration through the following relationships [67, 71].

$$S = \frac{8\pi k_B^2}{3eh^2} m^* T \left( \frac{\pi}{3n} \right)^{\frac{2}{3}} \quad (3.3)$$

$$\frac{1}{\rho} = ne\mu \quad (3.4)$$

$$K_e = L\sigma T = ne\mu LT \quad (3.5)$$

As shown in Equations 3.3 – 3.5,  $m^*$  is the effective mass of the carrier,  $\rho$  is the electrical resistivity,  $e$  is the charge of an electron,  $k_B$  is the Boltzmann constant,  $\mu$  is the carrier mobility,  $n$  is the carrier concentration, and  $L$  is the Lorenz number. Because  $\mu \propto 1/m^*$ , if  $m^*$  increases, the Seebeck,  $S$ , increases. The conductivity, however, will inherently decrease. With an increase in  $n$ , the electrical conductivity increases, however,  $S$  decreases. Therefore, the power factor  $S^2\sigma T$ , can be optimized typically in narrow-gap semiconducting materials as a function of carrier concentration ( $\sim 10^{19}$  carriers/cm<sup>3</sup>), to give the largest  $ZT$  [67, 68, 71]. To obtain good TE performance, ideal Seebeck values on the order of  $\sim 200$  V/K or greater and electrical conductivity close to  $\sim 10^3$   $\Omega^{-1}$  cm<sup>-1</sup> must be achieved [67, 68, 71].

The total thermal conductivity does increase with increasing carrier concentration and consequentially decreases the overall  $ZT$ . The electrical conductivity and the thermal conductivity are interrelated, in that  $\sigma$  is proportional to  $k_e$  through the Wiedemann–Franz relationship represented in Equation 3.5 (Lorentz number  $L = 2.45 \times 10^{-8}$  W $\Omega/K^2$ ) [67].

The lattice thermal conductivity  $K_L$  is independent of the carrier concentration and is represented in Equation 3.6, with  $\nu_s$  representing the effective velocity of sound through the material,  $C$  as the heat capacity, and  $L_{ph}$  as the mean free path of the phonons [68].

$$K_L \propto \nu_s C L_{ph} \quad (3.6)$$

At higher temperatures ( $T > 300$  K), the sound velocity and the heat capacity become temperature-independent. Therefore, the magnitude of  $K_L$  is determined by the mean free path of the phonons. Thus, when the phonons have a mean free path almost equal to the interatomic spacing of the constituent atoms, a minimum lattice thermal conductivity can be achieved. If  $K_L$  is equal to  $0 \text{ Wm}^{-1}\text{K}^{-1}$ ,  $K_T=K_e$ . From this and incorporating Wiedemann-Franz relationship (Equation 3.5) to Equation 3.1,  $ZT=S^2/L_0$ . Thus, to obtain a  $ZT = 1$ ,  $S= 157 \text{ V/K}$ . The concept "phonon-glass/electron-crystal" is of interest in which the phonon scattering properties behave as an amorphous material and the electrical properties behave as a crystalline material [79]. A variety of approaches have been explored to reduce the lattice part of the thermal conductivity while still maintaining desired electrical properties.

### 3.4 Methods to Improve $ZT$

Various strategies have been applied to improve  $ZT$ . Optimizing the carrier concentration and various band engineering approaches have been investigated to decouple  $\sigma$  and  $S$  and achieve a high power factor [71, 80–82]. Nano-structure engineering has been shown to effectively reduce the total thermal conductivity,  $K_T$ , without sacrificing the electrical transport of TE materials [82–84]. Other approaches to optimize  $ZT$  are alloying and transition metal/pnictogen-site doping [70, 72, 85–87]. Another method to maximize  $ZT$  is by filling the unoccupied large empty cages within M cube skutterudite framework with an ion [88–90]. The

size difference between the corresponding filler atom and void site enables the filler atom to act as an independent oscillator and thus dampen the thermal phonon conductivity.

### 3.4.1 Skutterudites: Strong Thermoelectric Candidates

Because of the unique structure and recognized ability to tune key transport properties, skutterudites are known to be strong thermoelectric candidates. The skutterudites are one well known class of Zintl compounds. As shown in Figure 3.5, the skutterudite crystal structure can be described as a repeated corner-sharing  $\text{MX}_6$  arrangement with two  $\text{M}_4\text{X}_{12}$  formula units and two large empty cages per unit cell, where M is a transition metal atom ( $\text{M} = \text{Fe}, \text{Co}, \text{Rh}, \text{or Ir}$ ) and X is a pnictogen atom ( $\text{X} = \text{P}, \text{As or Sb}$ ).

The general formula is  $\text{MX}_3$  with cubic space group  $Im\bar{3}$ . Because of the large size difference between the corresponding filler atom and void site, the filler atom can conceivably act as an independent oscillator and thus dampen the thermal phonon conductivity and decrease the total thermal conductivity [88–92]. Filling skutterudite voids can also influence the electrical conductivity, albeit the effect is usually negligible with respect to the decrease in total thermal conductivity [72, 88, 90, 92].

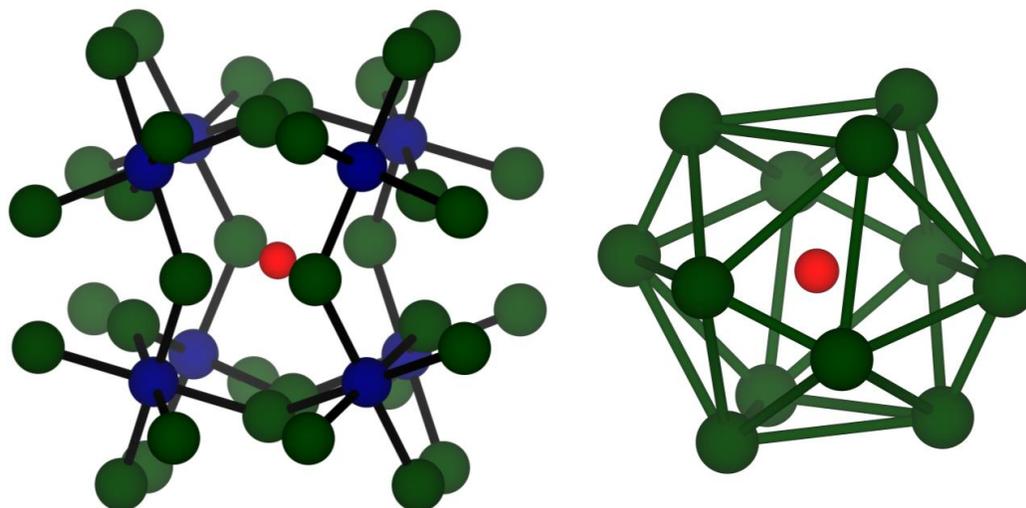

Figure 3.5: Skutterudite crystal structure shown as a repeated corner-sharing  $MX_6$  arrangement (left), and the resulting icosahedron cage site (right). M is a transition metal atom ( $M = \text{Fe}, \text{Co}, \text{Rh}, \text{or Ir}$ ) represented as blue spheres, and X is a pnictogen atom ( $X = \text{P}, \text{As or Sb}$ ) represented as green spheres. The red sphere represents the "rattler" element within the icosahedron void cage.

### 3.5 Conclusion

Thermoelectric generators (TEGs) are power-generation devices that are designed to convert waste heat into electrical energy. They can also be used as solid-state refrigeration devices, eliminating the need for CFC chemicals. There are several advantages to use TEGs; TEGs can collect waste heat covering a very wide temperature range without any vibration, noise, or gas emissions, and with very little maintenance requirements. Unfortunately, "good" TE materials possess 10-20% energy conversion efficiency. Various strategies have been applied to improve TE efficiency. Such methods have been by optimizing the carrier concentration and

band engineering approaches. Nano-structure engineering has also been shown to effectively reduce the total thermal conductivity,  $K_T$ , without sacrificing the electrical transport of TE materials. Other approaches to optimize  $ZT$  are alloying and transition metal/pnictogen-site doping. The concept "phonon-glass/electron-crystal" is of interest in which the phonon scattering properties behave as an amorphous material and the electrical properties behave as a crystalline material. A variety of approaches have been explored to reduce the lattice part of the thermal conductivity while still maintaining desired electrical properties. Filling the unoccupied large empty cages within M cube skutterudite framework with an ion to enhance phonon scattering and to increase the overall efficiency of the TE material is discussed.

## Chapter 4: Introduction to Pertinent Structure Types: Geometric and Structural Principles

### 4.1 Introduction

A variety of metal oxide and intermetallic structures were investigated. In this chapter, the geometric and structural principles of honeycomb layered  $A_2MO_3$ , spinel, perovskite, and the skutterudite structure will be discussed. Frustrated systems such as the honeycomb and spinel lattices have the potential to harbor exotic states such as quantum spin liquid behavior. Of recent interest for topological materials are perovskites where spin-orbit coupling is large enough to influence the electronic band structure. Because of the unique structure and recognized ability to tune key transport properties, skutterudites are known to be strong thermoelectric candidates. Understanding the structure is critical to establish a better understanding of the observed and/or predicted properties.

### 4.2 Honeycomb Layered Metal Oxide

The demonstration by Kitaev of an exactly solvable quantum spin liquid (QSL) model incorporating  $S = 1/2$  spins with anisotropic interactions on a honeycomb lattice [41] has motivated searches for its experimental realization. Honeycomb

layered  $A_2MO_3$  can be described as a rock salt ordered arrangement with  $2/3$  of the octahedral sites filled with A-cations and the remaining  $1/3$  filled with M-cations. All octahedral sites are edge shared. Figure 4.1 reveals the  $A_2MO_3$  ( $A = Na^+$  or  $Li^+$  and  $M = 3d, 4d$  or  $5d$  element) structure as alternating A and  $AM_2$  layers along the  $c$ -axis (left) and a single  $AM_2$  layer, where  $MO_6$  edge-sharing octahedra form the honeycomb framework (right). The A- $AM_2$  close packed stacking arrangement can vary, resulting in a variety of possible space groups.

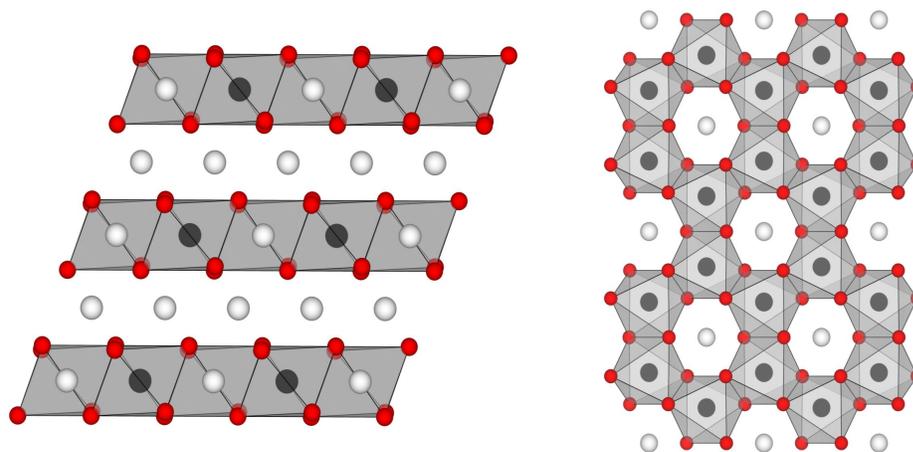

Figure 4.1: Left:  $A_2MO_3$  ( $A = Na^+$  or  $Li^+$  and  $M = 3d, 4d$  or  $5d$  element) structure as alternating A and  $AM_2$  layers. Right: Viewed along the  $c$ -axis the  $AM_2$  layer, where  $MO_6$  edge-sharing octahedra form the honeycomb lattice. White, black, and red spheres represent A, M, and oxygen atoms, respectively.

### 4.2.1 Stacking Sequences of the $AM_2$ Parallel Layers

The particular stacking arrangement between the  $AM_2$  parallel layers will only be taken into consideration as the close packing arrangement between a single A and  $AM_2$  layer remains unchanged. For representative  $AM_2$  layers defined as A, B, and C, there are multiple ABC stacking sequences of the equidistant, parallel layers. Starting with the A layer, the second B layer may be placed above the A layer with the  $A_1$  cation residing in the  $B_1$  void site to produce the  $A_1B_1$  stacking sequence (Figure 4.2). Though  $A_1B_2$  and  $A_1B_3$  are possible, they are related to  $A_1B_1$  by a  $120^\circ$  rotation and so are not unique. There are then two possibilities for the addition of a third layer, generating either  $A_1B_1C_1$  or  $A_1B_1C_2$  stacking, where repeating  $A_1B_1C_1$  blocks represent  $C2/m$  or  $C2/c$  and repeating  $A_1B_1C_2$  blocks represents  $P3_112$  (Figure 4.2) [93].

More complicated stacking arrangements are possible if the 3-layer blocks are combined in different manners. For example, repeating  $A_1B_1C_2-A_2B_3C_1$  blocks are possible (Figure 4.2). Clearly there are many stacking schemes for  $A_2MO_3$  based structures. Because the  $AM_2$  layers are separated by oxygen and lithium layers, the relative differences in energies between such possible 3-layer blocks are not significantly different, as long as close packing arrangement is achieved, therefore enabling a reasonable percentage of stacking fault imperfections (discussed in Chapter 5).

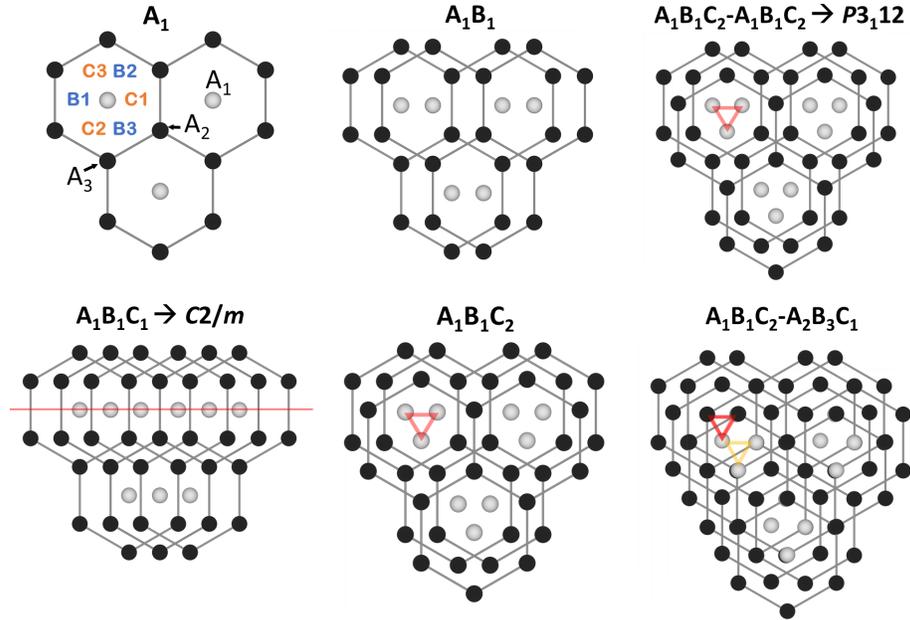

Figure 4.2: Illustrations generated by stacking  $AM_2$  ( $A = Na^+$  or  $Li^+$  and  $M = 3d$ ,  $4d$  or  $5d$  element) “honeycomb” layers with  $B_x$  and  $C_x$  ( $x = 1, 2$ , or  $3$ ) representing the locations in the  $ab$ -planes of the B and C holes in a close-packed array. The M and A ions are denoted by white and black (smaller) circles, respectively.

#### 4.2.2 Honeycomb Framework: Edge Shared Frustration

The  $A_2MO_3$  honeycomb structure is unique in that the slight variations in the M-M distances and angles of the three nearest  $MO_6$  edge sharing sites enables anisotropic behaviour unique to other systems (Figure 4.3) [33]. The magnetic superexchange between two adjacent M sites can occur via two exchange pathways as these octahedra are edge-sharing. Thus, destructive interference between the two Ir-O-Ir exchange pathways occurs, amplifying the electron correlation energy

and enhances spin frustration [33]. A honeycomb layer populated with heavy metals with large SOC enhances the electron correlation energy and the magnetic frustration [33]. It is therefore a balance between the degree of variation between the M-M distances and respective angles, orbital overlap, and the magnitude of SOC which tunes the electrical properties.

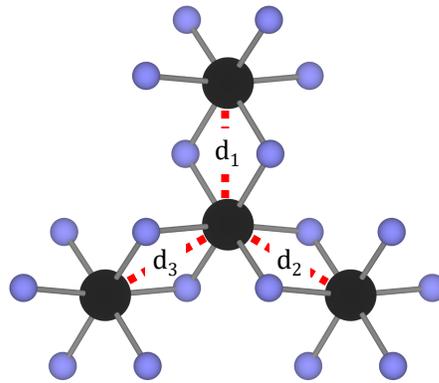

Figure 4.3: Illustration of the three MO<sub>6</sub> edge shared octahedra describing the honeycomb framework. The M-M distances ( $d_1$ ,  $d_2$ ,  $d_3$ ) are not equivalent and respective angles are not equal to  $120^\circ$ . Here, black and purple spheres represent M cations and oxygen, respectively.

## 4.3 Spinel Structure

### 4.3.1 Introduction

The frustrated spinel structure populated with large spin-orbit coupled (SOC) ions are an ideal setting for the exploration of exotic states. The general formula for a normal spinel is AB<sub>2</sub>O<sub>4</sub>, where the A-cation occupies tetrahedral sites and the B-

cation occupies octahedral sites (Figure 4.4) [94]. The  $B_2O_4$  network forms a rock salt structure with cubic close packed  $O^{2-}$  ions where only alternate octahedral sites are occupied by the B-cations (1/2 of the octahedral sites are occupied). The A-cation occupies 1/8 of the tetrahedral sites. Only tetrahedral sites with all four neighboring empty octahedral sites are filled (Figure 4.5). If all tetrahedral and/or all octahedral sites were filled, polyhedral face sharing would occur. Thus, cation-cation repulsion's do not allow adjacent octahedral and tetrahedral sites to be occupied simultaneously.

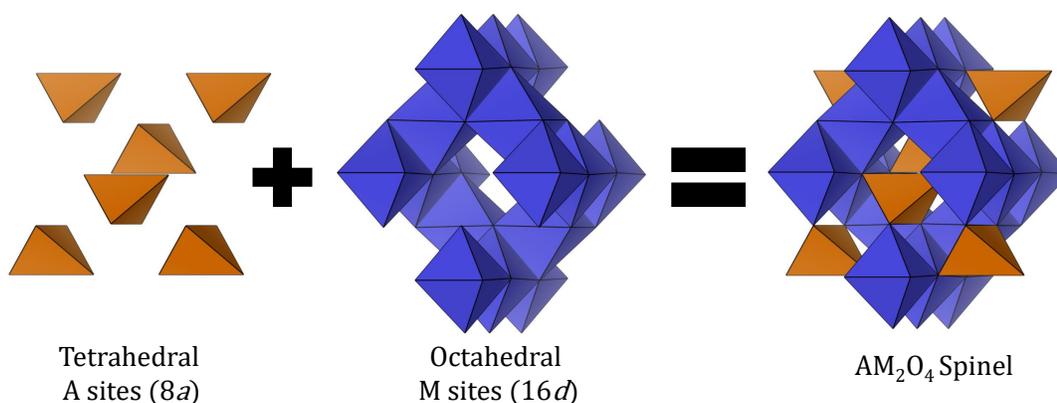

Figure 4.4: Illustration of the  $AB_2O_4$  spinel structure: isolated A-cation tetrahedral sites and the  $B_2O_4$  rock salt network where 1/2 of the octahedral sites are occupied.

One of the unique features of the spinel structure is that the B ions form a sublattice of corner-shared tetrahedra (Figure 4.6). This tetrahedral sub-lattice gives rise to strong magnetic frustration, if the B cations are magnetic and the magnetic coupling is antiferromagnetic. The A-ions also form a diamond sub-

lattice (Figure 4.6) and can also lead to strong magnetic frustration, if the A cations are magnetic and the magnetic coupling is antiferromagnetic.

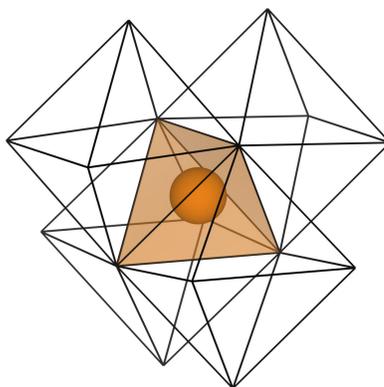

Figure 4.5: Illustration of an A-cation tetrahedral site with all four neighboring octahedral sites empty.

### 4.3.2 Cation Distribution in Spinel

The cation distribution between the A and B site may vary. In inverse spinels, half of the B ions occupy the tetrahedral sites, leaving all of the A ions and the remaining B ions occupying the octahedral sites, typically in a disordered arrangement. A complete range between normal and inverse spinels are possible. The cation distribution between the A and B sites can be quantified using the parameter  $\gamma$ ,  $[B_\gamma A_{1-\gamma}]^{tet}[A_\gamma B_{2-\gamma}]^{oct}O_4$  which represents the fraction of A ions on the octahedral sites [94]. Table 4.1 represents the stoichiometric identity of normal, inverse and random spinel systems.

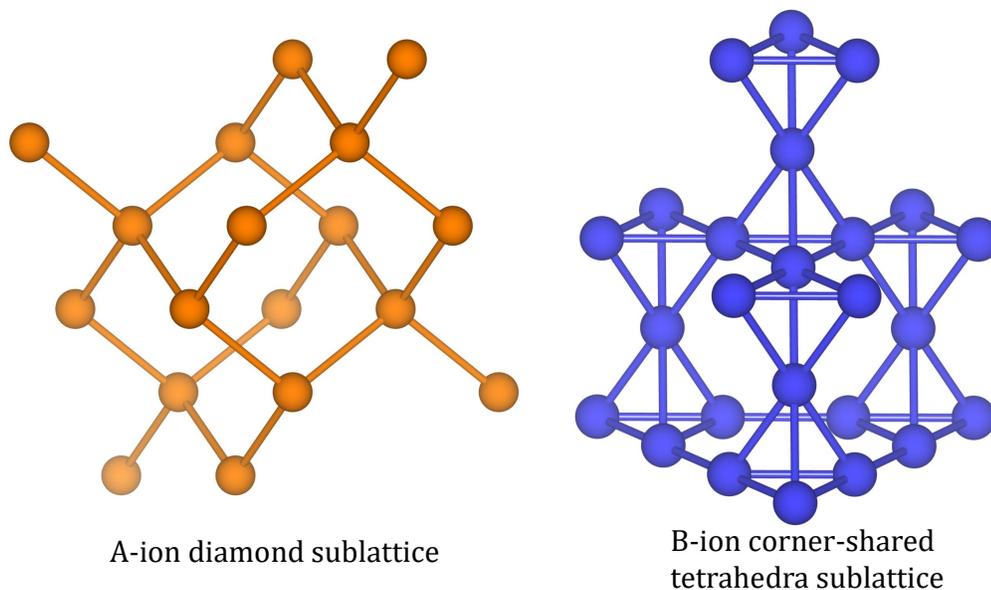

Figure 4.6: The A-ions form a diamond sublattice and the B-ions form a sublattice of corner-shared tetrahedra within the spinel structure.

Table 4.1: Classification of cation distribution in spinels

normal	$[A]^{tet}[B_2]^{oct}O_4$	$\gamma = 0$
random	$[B_\gamma A_{1-\gamma}]^{tet}[A_\gamma B_{2-\gamma}]^{oct}O_4$	$0 < \gamma < 1$
inverse	$[B]^{tet}[A, B]^{oct}O_4$	$\gamma = 1$

Several factors influence  $\gamma$ , such as covalent bonding effects, crystal field stabilization energy (CFSE), and cation size [10, 94]. For example,  $\text{Fe}_3\text{O}_4$  forms an inverse spinel. Here,  $\text{Fe}^{3+}$  is  $d^5$  and therefore has no preference for an octahedral site or tetrahedral site.  $\text{Fe}^{2+}$ , however, is  $d^6$  and from CFSE would prefer an

octahedral environment, thus forming  $[\text{Fe}^{3+}]^{tet}[\text{Fe}^{2+}, \text{Fe}^{3+}]^{oct}\text{O}_4$  [10].

## 4.4 Single and Double Perovskite Structures

### 4.4.1 Introduction

The perovskite structure class covers an enormous variety of compounds. Most of the ions in the periodic table can be incorporated into the perovskite structure with many different combinations of cations and anions. Because of this inherent flexibility, an array of properties are reported, with numerous examples where substitution of one or more of the cations can considerably impact structure and properties [95–101]. Of recent interest for topological materials are perovskites where SOC is large enough to influence the electronic band structure [102–104]. This review will encompass an introduction to the perovskite structure types, discussions on A- and B-site cation ordering within the  $\text{AA}'\text{BB}'\text{X}_6$  double perovskite framework, geometric and structural principles, and on ideal diffraction techniques for correct crystal structure determination of distorted perovskites.

### 4.4.2 Introduction to Perovskite Structure Types

The ideal cubic perovskite structure has an  $\text{ABX}_3$  stoichiometry and belongs to the space group  $Pm\bar{3}m$  [97]. The A-cation is surrounded by 12 X-anions forming a dodecahedral environment, the B-cation is octahedrally coordinated by six X-anions, and the X-anions are coordinated by two B-cations and four A-cations

(Figure 4.7 (a)). There are two ways to visualize the structure. The perovskite structure is more commonly described as a three-dimensional cubic network of corner-sharing  $BX_6$  octahedra, with the A-cation residing in the center of a cube defined by eight corner-sharing octahedral units (Figure 4.7 (b)). An alternative description is in terms of a cubic close-packed array of X-anions where one fourth of the X-anions are replaced with an A-cation in an ordered way to obtain a cubic close-packed  $AX_3$  arrangement. One fourth of the octahedral holes in the  $AX_3$  lattice are filled with B-cations, explicitly octahedral holes that do not border an A-cation (Figure 4.7 (c)).

The number of possible compounds is significantly expanded when multiple ions are replaced for one or more of the original ions in  $ABX_3$ . Substitution typically occurs on the cation sites, resulting in a large class of compounds known as double perovskites,  $AA'BB'X_6$  (Figure 4.7 (d)). When such substitutions are made, the cations can occupy the corresponding original site in either a random or an ordered fashion, resulting in a wide variety of lower symmetry systems. The electronegativity, charge, and size difference of the substituted cations can cause structural modifications such as cation ordering, octahedral distortion, and Jahn-Teller distortion [97,98].

Replacing one or more of the original ions in  $ABX_3$  can result in stoichiometric identities other than  $A_2BB'X_6$ . For example, 1:2 ordering of the B-cations can occur along [111] for an ideal 1:2 double perovskite, identified as  $A_3BB'_2X_9$  (Figure 4.8). There are many examples of perovskite-like systems. Perovskite-rock salt intergrowth structures such as the Ruddlesden-Popper phases are well estab-

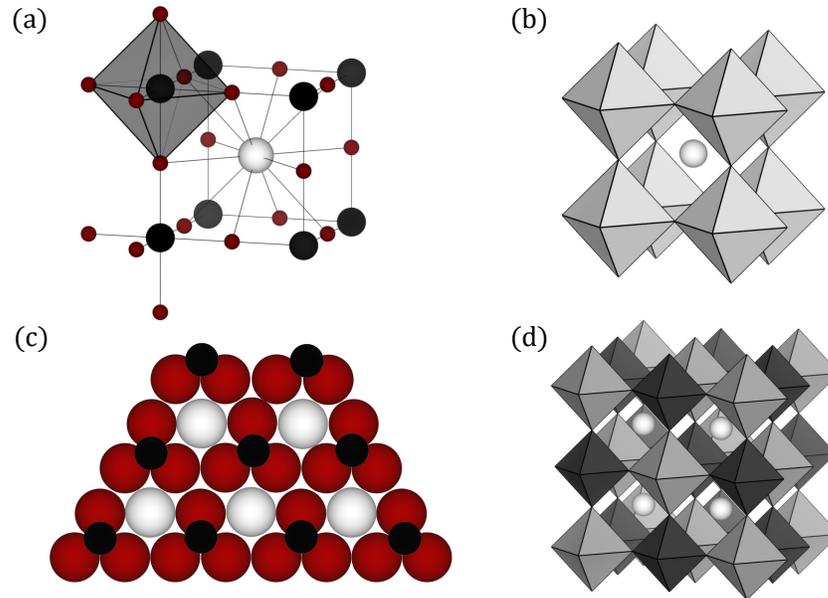

Figure 4.7: Illustrations of (a) the ideal cubic  $ABX_3$  perovskite framework with B-cations (black spheres) residing in octahedral sites and A-cations (white spheres) residing in a 12-coordinated dodecahedral environment, (b) three-dimensional cubic network of corner-sharing  $BX_6$  octahedra, with the A-cation residing in the center of a cube defined by eight corner-sharing octahedral units, (c) cubic close-packed  $AX_3$  arrangement with  $1/4$  of the octahedral holes filled with B-cations, and (d) double perovskite 1:1 rock salt ordered  $A_2BB'X_6$

lished [97]. Layered cuprates and related materials, such as  $La_2CuO_4$  are known superconductors [105–107], and  $Sr_2IrO_4$  is considered an ideal platform for exploring the quantum effects of magnetism in low-dimensional systems as the singular spin- $\frac{1}{2}$   $Ir^{4+}$  ions are arranged neatly in a square lattice [108]. For the context of this thesis, attention will be focused on the  $AA'BB'X_6$  structural framework for this chapter.

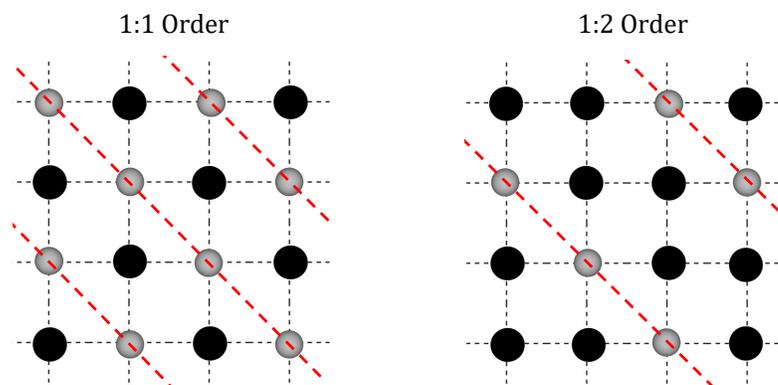

Figure 4.8: Illustration of 1:1 and 1:2 B-site cation ordering sequence in  $AA'BB'X_6$  (A-cations and X-anions are removed for clarity).

#### 4.4.3 A and B Site Cation Ordering in $AA'BB'X_6$

There are three types of ordering for both A and B-site cations within the double perovskite framework (Figure 4.9). For a double perovskite  $AA'BB'X_6$ , both A- and B-sites can order in rocksalt, layered, or columnar fashion with B-site ordering more common than A-site cation ordering [97, 98]. For the B-site rock-salt arrangement, all  $B'X_6$  octahedra are isolated from  $BX_6$  sites (Figure 4.9). For B-site layered arrangement, connectivity of  $B(B')X_6$  exists in two dimensional corner shared layers. For B-site columnar arrangement, connectivity of  $B(B')X_6$  exists in 1-dimensional corner shared chains (Figure 4.9). Rock-salt ordering is the most common. This can be explained in terms of electrostatic differences between the corresponding cations [97, 98]. Because all  $B'X_6$  octahedra are isolated from  $BX_6$  sites for the rock-salt arrangement, the more highly charged B' cations are separate

with six B cations as its nearest neighbor. Columnar ordering is the second most favorable with each B' cation having two B' cation and four B cation neighbors. Layered ordering is the least energetically favorable as each B' cation has four B' cation and two B cation neighbors. Relative to rock-salt ordering, only a few examples of layered and columnar ordering exist for  $A_2BB'X_6$ , systems [97]. For example, B-site layered ordering exists for  $La_2CuSnO_6$ , even though each  $Sn^{6+}$  has four  $Sn^{6+}$  neighbors [109]. It has been proposed Jahn-Teller distortion of  $Cu^{2+}$  plays an important role with stabilizing the system [97].

Most B-site columnar ordering exists with B/B' as the same element, but with mixed valency. For example, B-site columnar ordering exists in  $LaCaMn^{3+}Mn^{4+}O_6$  where Jahn-Teller distortion of  $Mn^{3+}$  also plays an important role with stability [110]. There are very few examples of A-site ordering in the double perovskite  $AA'BB'X_6$ . This, in part, can be explained by the restricted oxidation differences between A and A' cations. Unlike B/B' cations which can have an oxidation difference of up to seven [111], A/A' cations, in all known cases, have a maximum oxidation difference of only two. Most A-site cation ordering prefers layered ordering. To understand the preference of layered ordering, the anion nearest neighbor environment must be considered [98]. For a perovskite system, each anion has six nearest neighbor cations: two B-site cations and four A-site cations (Figure 4.10).

For B-site rock salt ordering, each anion environment is equivalent. Each anion is surrounded by one B-cation and B'-cation. Layered B-site ordering, however, creates three distinct anion environments, violating Pauling's fifth rule [112]. One of the distinct anion sites resides between two higher valent B' cations, causing

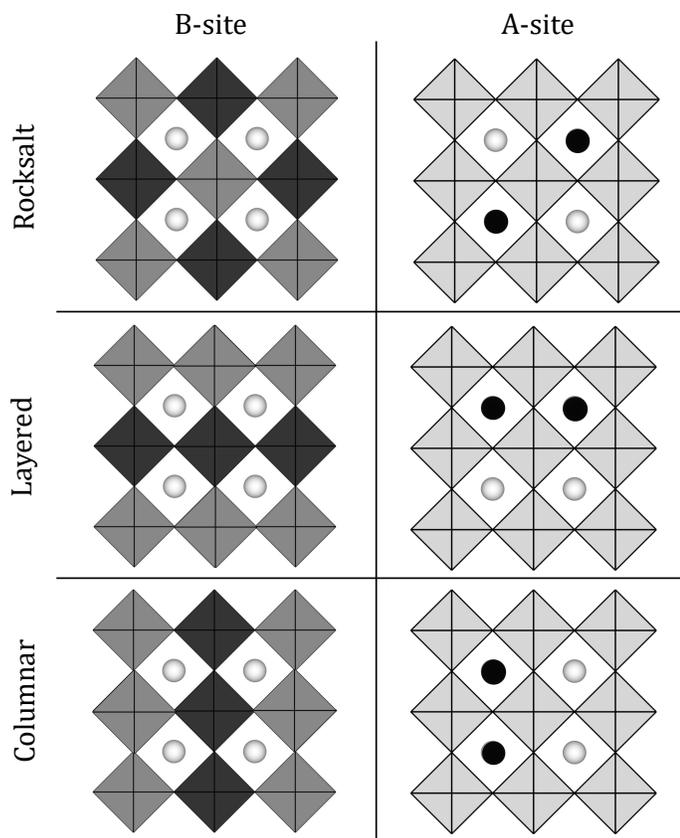

Figure 4.9: Cation ordering schemes in perovskites. From top to bottom rock salt, layered ordering, and columnar ordering are shown for B-site ordering in  $A_2BB'X_6$  perovskites (left) and for A-site ordering in  $AA'B_2X_6$  (right) perovskites.

over-bonding of the anion site (Pauling bond valence sum analysis [112]). The second anion site is between two lower valent B-cations, causing under-bonding of the anion site. The third anion site resides between B and B' cations, like the B-site rock salt ordering. Though A-site rock salt ordering does result in a single environment for all anions, the A-cations reside in a trans configuration (Figure 4.10), forcing A-X and A'-X bonds to be of equal length, even if A and

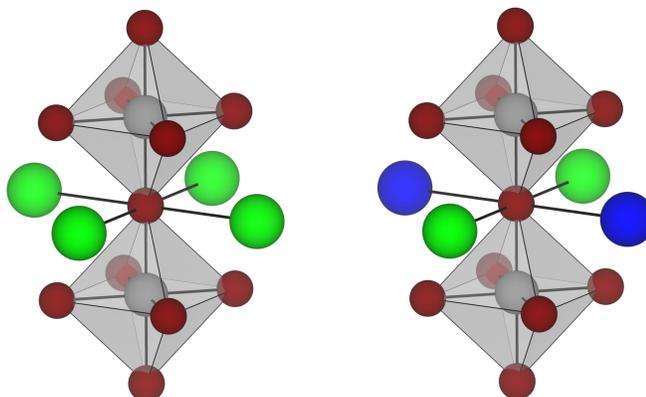

Figure 4.10: The anion environment in a primitive  $ABX_3$  perovskite and in a rock salt ordered  $AA'B_2X_6$  perovskite, where  $AA'$ ,  $B$ , and  $X$  are green/blue, grey, and red, respectively.

$A'$  cations are of different size [98]. Just like with layered B-site ordering, layered A-site ordering creates three distinct anion environments. However, because two thirds of the anions are surrounded by two A and two  $A'$  cations in a cis fashion, the anions can displace if there is a significant size difference between the A/ $A'$  cations. Regardless, the remaining one sixth of the anions are surrounded by four A-cations and the other one sixth are surrounded by four  $A'$ -cations, resulting in slight over- and under-bonding. To relieve such bonding instability, octahedral tilting and/or Jahn-Teller distortion of the B-site is needed in order for A-site ordering to occur [97, 98].

#### 4.4.4 Distorted Perovskites: Geometric and Structural Principles

For the perovskite  $ABX_3$ , structural distortions can occur depending on the size distribution between the A- and B-cations. For a cubic perovskite structure, the atomic radii are related to the unit cell dimension,  $a$ , by Equation 4.1.

$$a = \sqrt{2}(r_B + r_X) = r_A + r_X \quad (4.1)$$

The degree to which the cation sizes depart from Equation 4.1 is provided by the tolerance factor,  $\tau$  (Equation 4.2) [97].

$$\tau = \frac{r_A + r_X}{\sqrt{2}(r_B + r_X)} \quad (4.2)$$

The tolerance factor ( $\tau$ ) for a 1:1 ordered  $A_2BB'X_6$  perovskite [97] is represented in Equation 4.3.

$$\tau = \frac{r_A + r_X}{\sqrt{2}(0.5r_B + 0.5r_{B'}) + r_X} \quad (4.3)$$

For a cubic double perovskite system, if the tolerance factor ( $\tau$ ) is equal to 1.0, the A-X and B-X bonds can adopt their ideal lengths in the cubic structure. For  $\tau$  less than 1, the A-cation is too small for the 12-coordinated site and the perovskite structure can compensate for the cation size mismatch by tilting the  $BX_6$  octahedra and/or by distorting the ideal bond lengths [95–97].

If octahedral distortions occur to account for the cation size mismatch, the exact mechanism of octahedral distortion throughout the corner sharing  $B/B'X_6$

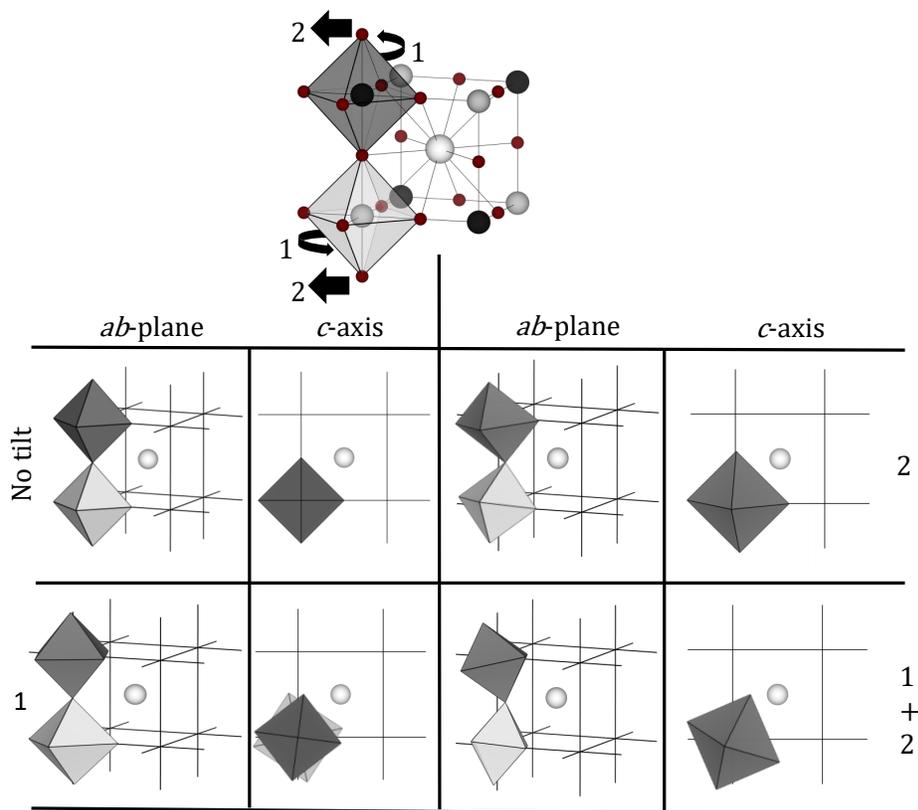

Figure 4.11: Mechanisms of octahedral distortion throughout the corner sharing B/B'X<sub>6</sub> framework.

framework can vary (Figure 4.11). If we consider a single octahedral B/B'X<sub>6</sub> site within the A<sub>2</sub>BB'X<sub>6</sub> framework, distortion can occur along the *ab*-plane in a clockwise or counterclockwise manner (Figure 4.11 – mechanism 1), can tilt along the *c*-axis (Figure 4.11 – mechanism 2), or via both mechanisms (Figure 4.11 – mechanisms 1 and 2) [97]. Throughout the corner sharing B/B'X<sub>6</sub> framework, the rotation/tilting can be the same between adjacent plains of octahedra, therefore

in-phase, or the rotation/tilting between adjacent plains of octahedra is opposite, and therefore out of phase. A classification scheme has been developed and is known as the Glazer tilt method [113].

For this method, possible rotation about the three axes of the octahedron is indicated by three letters  $a$ ,  $b$ , and  $c$ . If the degree of rotation about all three axes is the same, each letter will be the same, i.e.  $aaa$ , and if the degree of rotation is different for one of the axis, i.e.  $aac$ . To characterize if there is no rotation about an axis, the superscript “0” is provided for the letter. If rotation will be in-phase, the superscript “+” is provided, and for out of phase, the superscript “-” is provided. For the examples shown in Figure 4.12, rotation of octahedra about only one axis is shown. The difference between  $a^{\circ}a^{\circ}c^{-}$  and  $a^{\circ}a^{\circ}c^{+}$  is out of phase and in-phase between adjacent plains of octahedra, respectively. A list of Glazer tilt systems for  $ABX_3$  and  $A_2BB'X_6$  with no order, 1:1 order, and 1:2 order can be found elsewhere [97, 113–115].

#### 4.4.5 Ideal Diffraction Techniques for Correct Crystal Structure Determination

Knowing the correct crystal structure for a given compound is essential for understanding its properties. It is very common in literature where incorrect structures are determined mostly due to the limitations of the diffraction method used. Most  $A_2BB'X_6$  perovskites exhibit a high degree of pseudosymmetry, meaning slight deviations that characterize a non-ideal perovskite are subtle in these compounds.

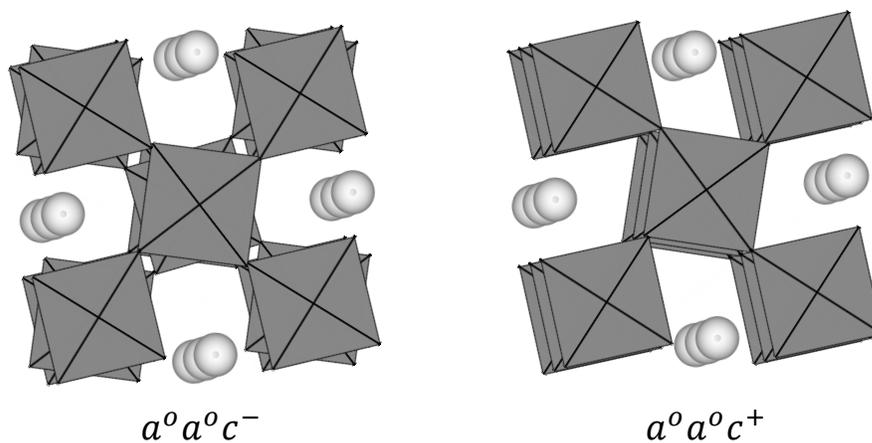

Figure 4.12: View looking down the  $c$ -axis of  $a^o a^o c^-$  and  $a^o a^o c^+$  with the B-site cations located at the center of the grey octahedral sites and A-site cations shown as white spheres.

Comparing compounds with the A-cation as  $\text{Ba}^{2+}$  or  $\text{Ca}^{2+}$  for  $\text{A}_2\text{BB}'\text{X}_6$ , the presence or lack of reflection splitting due to octahedral tilting distortions is often easily evident [95–97]. Most double perovskites containing  $\text{Ba}^{2+}$  do not distort from cubic symmetry and are therefore assigned to the  $a^o a^o a^o$  tilt system. For  $\text{Ca}^{2+}$  double perovskites, well-defined peak splitting with XRPD is observed and is commonly assigned to one of the 3-tilt Glazer systems [95–97]. For  $\text{Sr}^{2+}$  double perovskites, though octahedral distortion does occur to accommodate the smaller A-cation, XRPD peak splitting is not observed due to their high degree of pseudosymmetry. Therefore, space group assignment is challenging with XRPD methods. Because of its relatively small atomic number, oxygen has a poor X-ray scattering coefficient. Oxygen, however, has a coherent neutron scattering length comparable to heavier

atoms [116]. Therefore, neutron diffraction techniques are ideal to establish the right space group due to slight octahedral distortions.

## 4.5 Skutterudite

The skutterudites are one well known class of Zintl compounds. The Zintl concept is important in solid-state chemistry to explain how compounds that combine main group and electropositive elements can be stable for formulas that essentially do not make any sense [117]. For example, the stability of most ionic systems such as NaCl can easily be explained by fundamental concepts through which an electropositive ion donates electrons to an electronegative ion to achieve closed shell electron configurations. For Zintl phases, fundamental concepts of electron-counting and stability rules are not as straightforward. For such compounds, to obey fundamental electron counting, the electronegative elements form a polyatomic electron-accepting molecule inside the solid called a polyanion that fills its available energy states with electrons from the electropositive elements. For  $BX_3$  skutterudites with B a group 6 metal such as Co, Rh or Ir and X a pnictogen atom such as P, As or Sb, Zintl electron count of 24 valence electrons per formula unit must be followed [91]. Group 6 metals with 3+ oxidation state have the electron configuration  $nd^6$ . In octahedral coordination and low spin, they thus have a filled  $t_{2g}$  band and an empty  $e_g$  band. Square  $X_4$  Zintl polyanions form with a formal charge of 4-. Thus,  $M_4^{3+}(X_4)_3^{4-}$  is achieved [91]. As shown in Figure 4.13, the skutterudite crystal structure can be described in two ways: (left) a repeated

corner-sharing  $\text{MX}_6$  arrangement with two  $\text{M}_4\text{X}_{12}$  formula units and two large empty cages per unit cell, or (right) an open cage like structure of cube-connecting M atoms with three fourths of the void sites filled with  $\text{X}_4$  Zintl polyanions, where M is a transition metal atom ( $\text{M} = \text{Fe}, \text{Co}, \text{Rh}, \text{or Ir}$ ) and X is a pnictogen atom ( $\text{X} = \text{P}, \text{As or Sb}$ ). The general formula is  $\text{MX}_3$  with cubic space group  $Im\bar{3}$ . The M cations occupy the  $8c$  ( $1/4, 1/4, 1/4$ ) site and the X anions occupy the  $24g$  ( $0, y, z$ ) site with  $y \sim 0.15$  and  $z \sim 0.34$ .

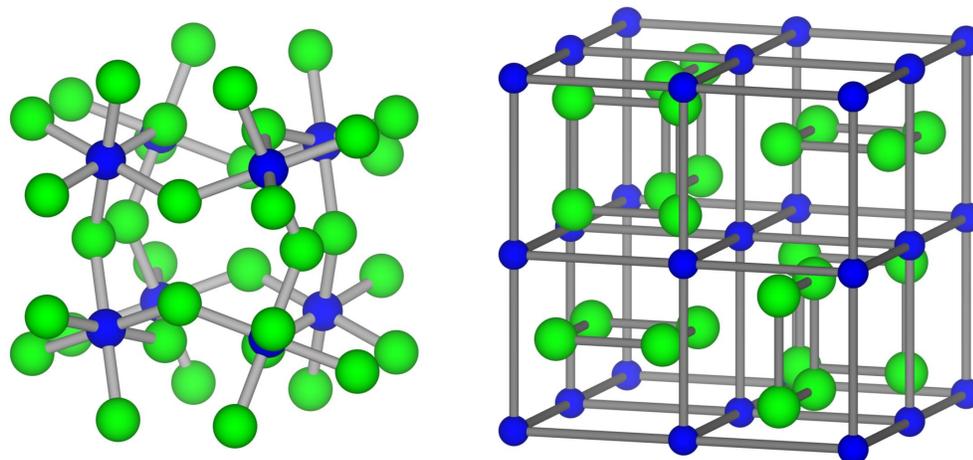

Figure 4.13: Skutterudite crystal structure shown as (a) a repeated corner-sharing  $\text{MX}_6$  arrangement and (b) cube-forming M atoms with three fourths of the void sites filled with  $\text{X}_4$  Zintl polyanions.

The empty cages can be filled by an ion A, leading to the formula  $\text{A}_y\text{M}_4\text{X}_{12}$  with  $y \leq 1$ . A filled  $\text{AB}_4\text{X}_{12}$  skutterudite is expected to be with an electron precise valence electron count of 96 ( $4 \times 24$ ) per formula unit [91], because  $\text{M}_4^{3+}(\text{X}_4)_3^{4-}$  with group-6 B metal and a  $p^6$  X atom configuration without any filler atom

has an electron count of 96. Therefore, only small amounts of the filler ion, A, can be incorporated, with the solubility limit of  $y$  in  $A_yM_4X_{12}$  typically close to 0.15 [88, 89, 91].

## 4.6 Conclusion

This review provides an introduction to the geometric and structural principles of honeycomb layered, spinel, perovskite, and skutterudite structures. Frustrated lattice systems such as the honeycomb or spinel structures have the potential to harbor novel enigmatic quantum states. For example, the demonstration by Kitaev of an exactly solvable quantum spin liquid (QSL) model incorporating  $S = 1/2$  spins with anisotropic interactions on a honeycomb lattice has motivated searches for its experimental realization as a potential quantum spin liquid system. Understanding the structure is critical to establish a better understanding of the observed and/or predicted properties.

## Chapter 5: Modeling Stacking Faults of Honeycomb Layered A<sub>2</sub>MO<sub>3</sub> Metal Oxide Systems

### 5.1 Introduction

It is well known the presence of imperfections in the crystal lattice can influence the electrical properties of polycrystalline systems. A stacking fault is one such imperfection, which occurs within systems that consist of parallel layers that allow for translations parallel to the layers and rotations about the layer normal [93]. Honeycomb layered A<sub>2</sub>MO<sub>3</sub> metal oxide systems are known to possess such stacking faults [43, 93, 118, 119]. A review of the honeycomb layered A<sub>2</sub>MO<sub>3</sub> structure is provided in Chapter 4.

### 5.2 Stacking Sequences of the AM<sub>2</sub> Parallel Layers

As discussed in Chapter 4, for AM<sub>2</sub> layers defined as A, B, and C, there are two ABC stacking sequences of the equidistant, parallel layers. Starting with the A<sub>1</sub> layer, a second layer may be placed above this to produce A<sub>1</sub>B<sub>1</sub>. Though A<sub>1</sub>B<sub>2</sub> and A<sub>1</sub>B<sub>3</sub> are possible, they are related to A<sub>1</sub>B<sub>1</sub> by a 120° rotation and so are not unique. There are then two possibilities for the addition of a third layer, generating either A<sub>1</sub>B<sub>1</sub>C<sub>1</sub> or A<sub>1</sub>B<sub>1</sub>C<sub>2</sub> stacking, where repeating A<sub>1</sub>B<sub>1</sub>C<sub>1</sub> blocks represent *C2/m*

and repeating  $A_1B_1C_2$  blocks represents  $P3_112$  [93]. More complicated stacking arrangements are possible if the 3-layer blocks are combined in different manners. Therefore, there are many stacking schemes for  $A_2MO_3$  based structures. Because the  $AM_2$  layers are separated by oxygen and lithium layers, the relative differences in coulomb repulsion energy between these possible 3-layer blocks are not significantly different, therefore enabling the possibility of a reasonable percentage of stacking fault imperfections.

### 5.3 Modeling Stacking Faults

Current refinement software, such as GSAS, cannot refine stacking fault contribution, as shifting  $AM_2$  layers will not equate to the corresponding assigned space group. To model stacking fault contribution, the DIFFaX software or FAULTS software must be used. Both DIFFaX and FAULTS software require a text file of which instrumental parameters, unit cell and atomic information, and transition vectors describing interlayer connections are provided. Example input files for both software's are provided in Appendix C and D.

#### 5.3.1 DIFFaX Program

The DIFFaX software requires the cell axes to be defined such that the  $c$ -axis is perpendicular to the fault direction, resulting with a new idealized unit cell. As an example, for a monoclinic system with space group  $C2/m$ , a hexagonal

unit cell with  $a=a_{(C2/m)}$  and  $c_{hex}=c_{(C2/m)}\times\cos(\beta_{(C2/m)}-90)$  can be implemented (Figure 5.1). For this example, only  $AM_2$  layers are taken into consideration, with oxygen and A-cation interlayers omitted for simplicity. By repeating the hexagonal unit cell along the  $a-b$  plane, the atomic positions for the three atoms within the hexagonal unit cell (Figure 5.1) can replicate the honeycomb framework. For this example, two equidistant and parallel  $AM_2$  layers characterize ideal monoclinic  $C2/m$  system with one layer perpendicular to the  $c$ -axis origin and the second layer equating to the  $c$ -axis. For the defined DIFFaX unit cell, only a single  $AM_2$  layer will be demarcated and perpendicular to the  $c$ -axis origin (Figure 5.1). Table 5.1 provides an example of atomic coordinates within the DIFFaX hexagonal unit cell representing  $A_2MO_3$ .

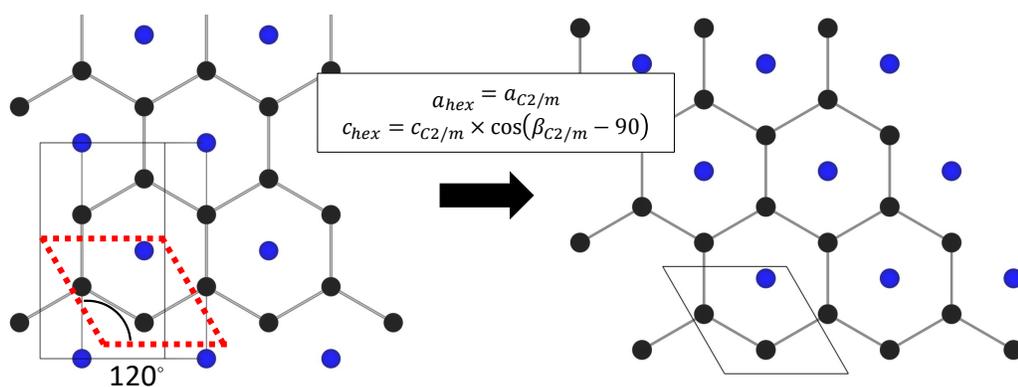

Figure 5.1: Schematic of a  $AM_2$  “honeycomb” layer along the  $a - b$  plain ( $C2/m$  unit cell) and the new idealized DIFFaX hexagonal unit cell (red dash) with black and blue representing the M transition metal and the A-cation, respectively.

O	4/9	5/9	1/4	1.0
O	7/9	2/9	1/4	1.0
A	1/9	2/9	1/2	1.0
A	4/9	8/9	1/2	1.0
A	7/9	5/9	1/2	1.0
O	1/9	5/9	3/4	1.0
O	4/9	2/9	3/4	1.0
O	7/9	8/9	3/4	1.0

a) unit cell dimensions:  $a=b=5.18 \text{ \AA}$ ,  $c=4.80 \text{ \AA}$ ,  $\alpha = \beta = 90.0^\circ$ , and  $\gamma = 120.0^\circ$ .

To determine the vectors associated with the interlayer stacking sequence, the close packing arrangement must be taken into consideration. As illustrated in Figure 5.2, the stacking sequence begins with a single  $AM_2$  layer, and based on the close packing arrangement of oxygen, the A-cation layer and subsequently the next  $AM_2$  layer are placed accordingly. Thus, to replicate the ideal  $A_1B_1C_1$  stacking sequence of  $A_2MO_3$  ( $C2/m$ ), for the given DIFFaX unit cell, the layer sequencing must be characterized by the  $[\frac{1}{3}, 0, 1]$  transition vector ( $R_1$ ) (Figure 5.3). To replicate stacking fault contribution, transition vectors  $[\frac{1}{3}, \frac{1}{3}, 1]$  and  $[0, \frac{1}{3}, 1]$  ( $R_2$  and  $R_3$ ) can be used (Figure 5.3).

Illustrations representing the influence of varying the vector assignment between three  $AM_2$  layers are shown in Figure 5.3. Figure 5.3 (b) illustrates the

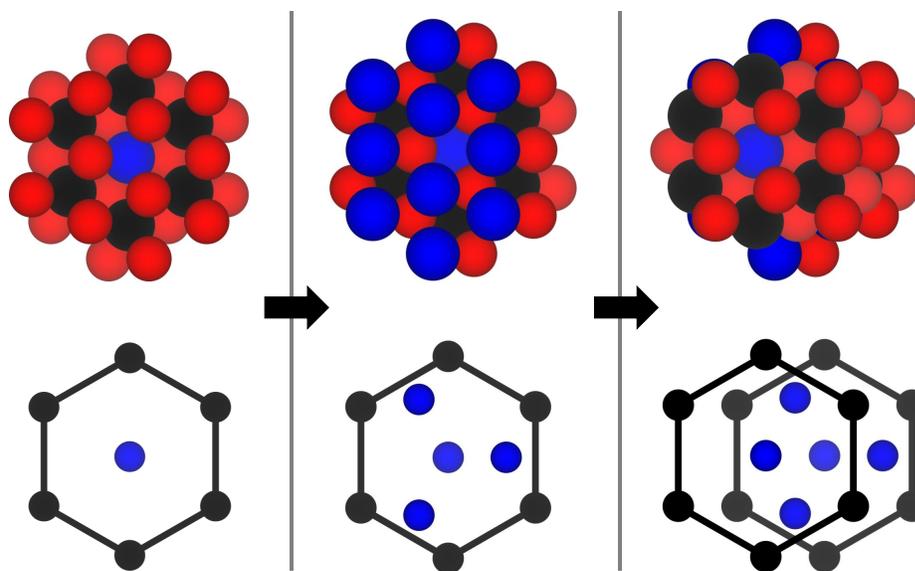

Figure 5.2: Illustration of the close packing stacking arrangement of oxygen (red), A-cations (blue), and M-cations (black) for a honeycomb  $A_2MO_3$  down the  $c$ -axis. Top illustrations represent all atoms in space-filling form with the bottom illustrations representing only the A- and M-cations for a single honeycomb ring.

ideal  $A_1B_1C_1$  stacking sequence of monoclinic  $A_2MO_3$  ( $C2/m$ ). For each transition vector ( $R_x$ ) that describes the transition from one DIFFaX unit cell to another, a probability ( $\alpha_x$ ) must be assigned. For the example provided, probabilities must be assigned to each of the three transition vectors, with  $\alpha_1 + \alpha_2 + \alpha_3 = 1$  for each layer.

Figure 5.4 shows a comparison of XRPD of  $Li_2IrO_3$  ( $C2/m$ ) and the calculated XRPD of  $Li_2IrO_3$  DIFFaX model with  $\alpha_1 = 0.98$  and  $\alpha_2 = \alpha_3$ . For the model presented, Li-Ir site disorder within the  $LiIr_2$  layers was implemented with Ir(4g)/Li(2a) occupancies set to 0.85. Calculated XRPD of  $Li_2IrO_3$  DIFFaX model

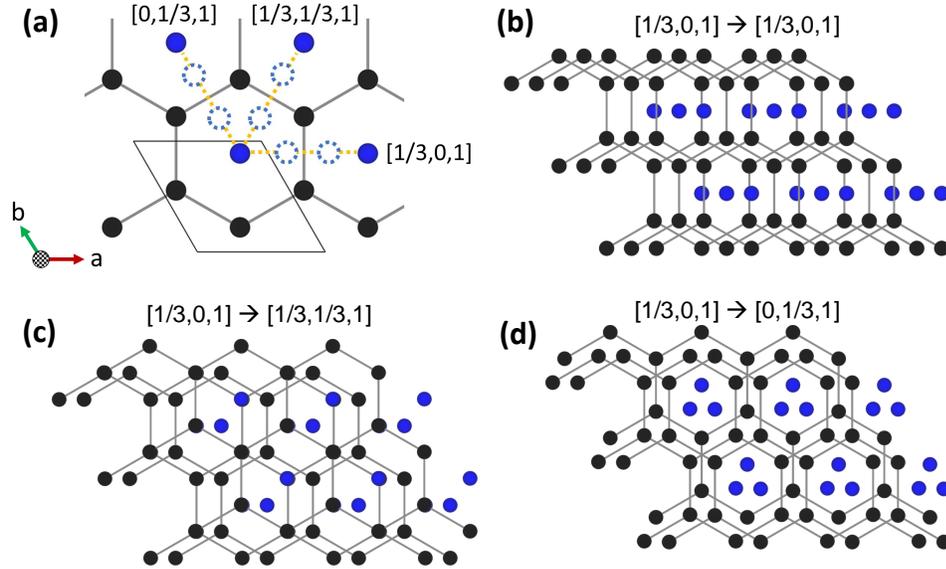

Figure 5.3: Possible stacking sequences between  $AM_2$  layers, based on the given DIFFaX unit cell described in the text, with  $[\frac{1}{3}, 0, 1]$  transition vector ( $R_1$ ) representing the ideal  $A_1B_1C_1$  stacking sequence of  $A_2MO_3$  ( $C2/m$ ), and transition vectors  $[\frac{1}{3}, \frac{1}{3}, 1]$  and  $[0, \frac{1}{3}, 1]$  ( $R_2$  and  $R_3$ ) describing stacking fault contribution (a). Illustrations representing the influence of varying the vector assignment between three DIFFaX unit cells are shown (b-d), with (b) representing the ideal  $A_1B_1C_1$  stacking sequence of monoclinic  $A_2MO_3$  ( $C2/m$ ).

with  $\alpha_1$  ranging from 1 to 0.5 are shown in Figure 5.5. For the model presented,  $\alpha_2 = \alpha_3$  and Li-Ir site disorder within the  $LiIr_2$  layers was implemented with  $Ir(4g)/Li(2a)$  occupancies set to 0.85.

With incorporation of stacking faults, only (002) and (020) peaks within 17 – 35  $2\theta$  range do not broaden (Figure 5.5). Similar observations for other DIFFaX modeled  $Li_2MO_3$  systems exist [43, 93, 118, 119]. The absence of the (020) peak is therefore attributed to Li-Ir site disorder within the  $LiIr_2$  layers.

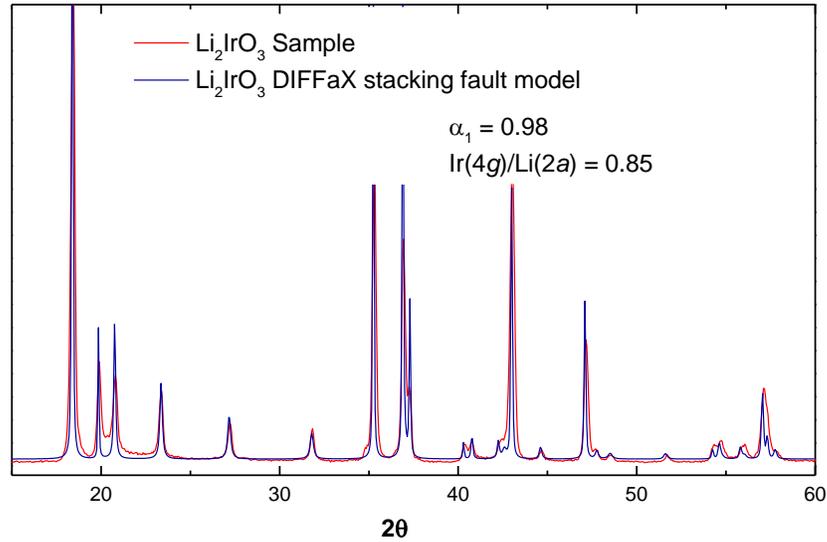

Figure 5.4: A comparison of XRPD of  $\text{Li}_2\text{IrO}_3$  ( $C2/m$ ) and the calculated XRPD of  $\text{Li}_2\text{IrO}_3$  DIFFaX model with  $\alpha_1 = 0.98$  and  $\alpha_2 = \alpha_3$ . For the model presented, Li-Ir site disorder within the  $\text{LiIr}_2$  layers was implemented with  $\text{Ir}(4g)/\text{Li}(2a)$  occupancies set to 0.85.

### 5.3.2 FAULTS Program

The FAULTS program also requires the cell axes to be defined with the  $c$ -axis perpendicular to the fault direction. A new unit cell for each individual layer must therefore be established. As an example, for a monoclinic system  $\text{A}_2\text{MO}_3$  with space group  $C2/c$ , the new hexagonal unit cell can be defined as  $a_{hex} = a_{(C2/c)}$  and  $c_{hex} = [c_{(C2/c)} \times \cos(\beta_{(C2/c)} - 90) / 2](z)$ , with  $z$  as the number of hexagonal layers used for the model. Division of 2 is based on the number of repeating Li- $\text{LiM}_2$  layers within  $C2/c$  unit cell. The single layer used and A- $\text{AM}_2$   $C2/c$  layer are

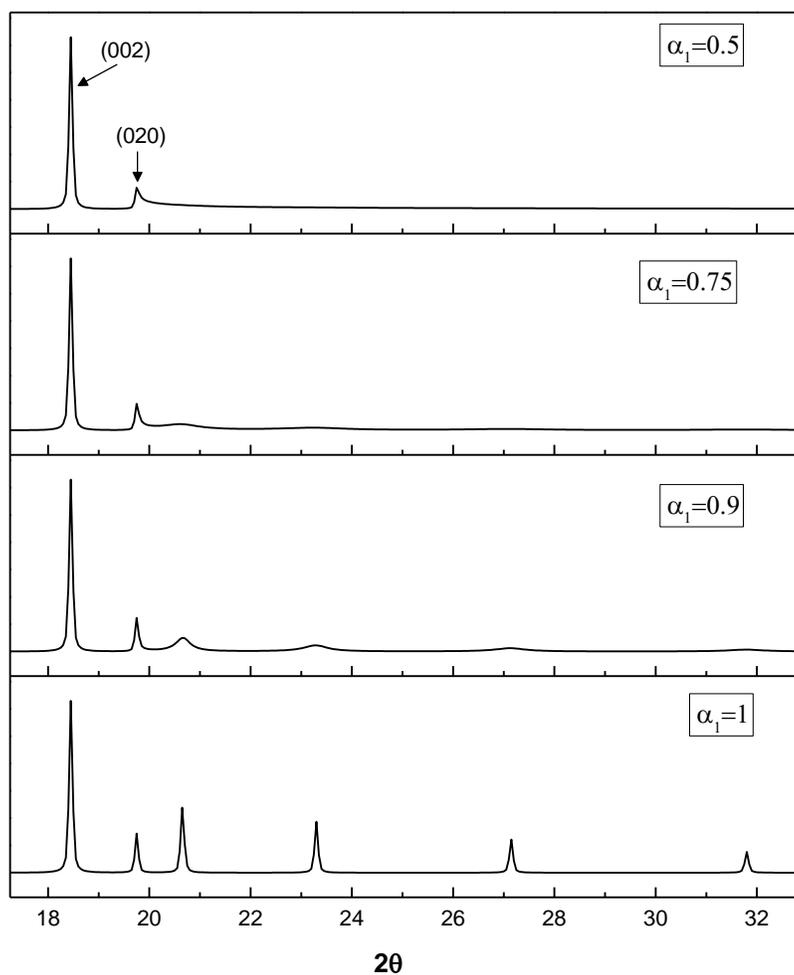

Figure 5.5: Calculated XRPD of  $\text{Li}_2\text{IrO}_3$  DIFFaX model with  $\alpha_1$  from 1 to 0.5 and  $\alpha_2 = \alpha_3$ . For the model presented, Li-Ir site disorder within the  $\text{LiIr}_2$  layers was implemented with Ir(4g)/Li(2a) occupancies set to 0.85.

illustrated in Figure 5.6. Table 5.2 provides the atomic coordinates within the FAULTS hexagonal unit cell represented in Figure 5.6. To replicate the ideal

stacking sequence of  $A_2MO_3$  ( $C2/c$ ), layer sequencing can be characterized by  $[\frac{1}{3}, 0, \frac{1}{z}]$  transition vector ( $R_1$ ). To replicate stacking fault contribution, transition vectors  $[0, \frac{1}{3}, \frac{1}{z}]$  and  $[\frac{2}{3}, 0, \frac{1}{z}]$  ( $R_2$  and  $R_3$ ) must be incorporated. Probabilities must be assigned to each of the three transition vectors, with  $\alpha_1 + \alpha_2 + \alpha_3 = 1$  for each layer.

## Chapter 6: Local Moment Instability of Os in Honeycomb

### 6.1 Abstract

Compounds with honeycomb structures occupied by strong spin orbit coupled (SOC) moments are considered to be candidate Kitaev quantum spin liquids. Here we present the first example of Os on a honeycomb structure,  $\text{Li}_{2.15(3)}\text{Os}_{0.85(3)}\text{O}_3$  ( $C2/c$ ,  $a = 5.09 \text{ \AA}$ ,  $b = 8.81 \text{ \AA}$ ,  $c = 9.83 \text{ \AA}$ ,  $\beta = 99.3^\circ$ ). Neutron diffraction shows large site disorder in the honeycomb layer and X-ray absorption spectroscopy indicates a valence state of Os ( $4.7 \pm 0.2$ ), consistent with the nominal concentration. We observe a transport band gap of  $\Delta = 243 \pm 23 \text{ meV}$ , a large van Vleck susceptibility, and an effective moment of  $0.85 \mu_B$ , much lower than expected from 70% Os(+5). No evidence of long range order is found above 0.10 K but a spin glass-like peak in ac-susceptibility is observed at 0.5 K. The specific heat displays an impurity spin contribution in addition to a power law  $\propto T^{(0.63 \pm 0.06)}$ . Applied density functional theory (DFT) leads to a reduced moment, suggesting incipient itineracy of the valence electrons, and finding evidence that Li over stoichiometry leads to Os(4+)-Os(5+) mixed valence. This local picture is discussed in light of the site disorder and a possible underlying quantum spin liquid state.

## 6.2 Introduction

The demonstration by Kitaev of an exactly solvable quantum spin liquid (QSL) model incorporating  $S = \frac{1}{2}$  spins with anisotropic interactions on a honeycomb lattice [120, 121] has motivated searches for its experimental realization. Whereas magnetic honeycomb-containing compounds have been extensively investigated in 3d and 4d metal oxides [122–130], the strong interaction anisotropy required by Kitaev’s theory has placed a focus on 5d metal oxides, for which strong spin-orbit coupling (SOC), the origin of spatial anisotropy, can be expected [131–137]. In the  $A_2MO_3$  honeycomb structure, where A is an alkali element and M a 4d or 5d element, the  $AM_2$  layers form a hexagonal network of edge sharing  $MO_6$  octahedra with a single  $A^+$  ion at the centers of the hexagons (Figure 1).

Examples such as  $\alpha$ - $Na_2IrO_3$  and  $\alpha$ - $Li_2IrO_3$  with effective spin  $J_{eff} = \frac{1}{2}$ , have recently emerged as possible examples of Kitaev physics. These compounds possess antiferromagnetic (AF) Weiss temperatures of 125(6) K and 33(3) K and undergo AF order at 15.5 K and 14.5 K for  $Na_2IrO_3$  and  $Li_2IrO_3$  respectively [138, 139]. The 3D hyper-honeycomb lattice compound  $\beta$ - $Li_2IrO_3$ , however, demonstrates a ferromagnetic (FM) Weiss temperature of 40 K and weak ordering signatures at 38 K among  $J_{eff} = \frac{1}{2}$  moments [140]. Among non-oxide materials, the layered compound  $\alpha$ - $RuCl_3$  has also been discussed as a possible Kitaev system, though it too undergoes long range order at 7.5 K [141]. Since the suppression of classical order via geometrical frustration is a requirement for creating a QSL state, the above systems, while possessing important attributes, fall short of the Kitaev

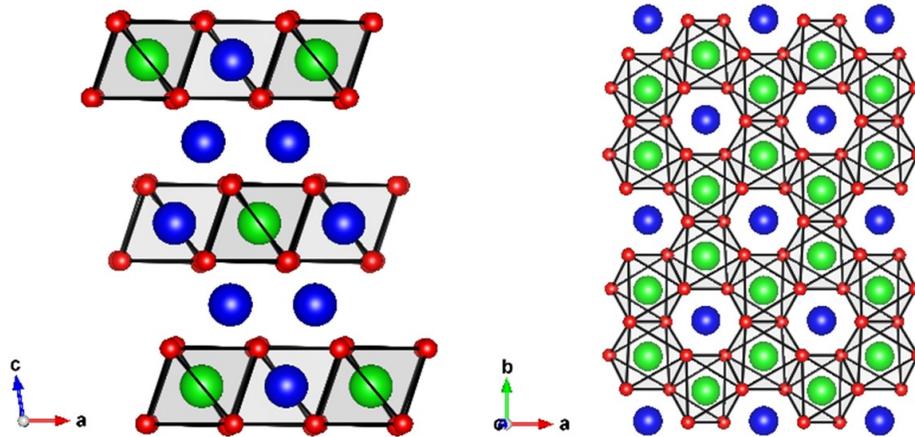

Figure 6.1: Left:  $\text{Li}_2\text{MO}_3$  ( $M = 4d$  or  $5d$  element) structure as alternating Li and  $\text{LiM}_2$  layers. Right: Viewed along the  $c$  axis the  $\text{LiM}_2$  layer, where  $\text{MO}_6$  edge-sharing octahedra form the honeycomb lattice. Blue, green, and red spheres represent lithium, metal, and oxygen atoms respectively.

criteria [142]. Due to the ordering seen in other honeycomb compounds and because the specific materials conditions required to produce a QSL are ill-defined at present, it is important to study other honeycomb-containing compounds with sizable SOC.

Here, we ask what would be the result of *reducing* the SOC from that of 540 meV in Ir to 480 meV in Os [143]. In the present work we report on the synthesis, structure, and properties of  $\text{Li}_{2.15(3)}\text{Os}_{0.85(3)}\text{O}_3$  which is isostructural to the Ir honeycomb compounds mentioned above. For the stoichiometric compound,  $\text{Li}_2\text{OsO}_3$ , the Os ion is expected to be in the  $4+ = d^4$ ,  $J_{eff} = 0$  state to maintain charge-neutrality. In our work, we find, in contrast to other honeycomb systems, a lack of

long range order above 0.1K. While this might be due to a frustrated lattice, it also might be due to site disorder among the Os ions. For each crystallographic site representing the  $\text{LiOs}_2$  layer, an average of 43% of the sites (compared to the expected 33% of these sites) are occupied by lithium and thus the average valence of Os is  $+4.5 \pm 0.1$  ( $d^{3.5}$ ), a value consistent with our X-ray absorption spectroscopy (XAS) measurements, which yield  $+4.7 \pm 0.2$ . From a local moment perspective and using the XAS-determined valence state, our system might be comprised of 30%  $d^4$  ( $J_{eff} = 0$ ) and 70%  $d^3$  ( $J_{eff} = \frac{3}{2}$ ) but its physical properties are not easily understood. We find a transport gap of 243 meV, an effective magnetic moment of  $0.85 \mu_B$ , which is much less than the effective moment of  $3.24 \mu_B$  expected if 70% of the ions possessed  $J_{eff} = \frac{3}{2}$ . No magnetic order is observed above 0.10 K, and the specific heat obeys a fractional power law in temperature and is only weakly magnetic field-dependent. We discuss the constraints on the local physics of Os from a band structure perspective and their implications for collective behavior en route to a possible QSL in SOC honeycomb systems.

## 6.3 Results and Discussion

### 6.3.1 Structure

Common space groups assigned to honeycomb-structure compounds  $\text{Li}_2\text{MO}_3$  (M = Mo, Mn, Rh, Ir, Ru, Pt, and Sn) are  $C2/m$ ,  $C2/c$ , and  $R\bar{3}m$  [123, 126–128, 130, 136, 144–151]. Figure 6.2 represents  $\text{Li}_2\text{MO}_3$   $C2/m$ ,  $C2/c$ , and  $R\bar{3}m$  unit

cells illustrated down the b-axis (top) and corresponding portion of the Li-M layer representing a single hexagon configuration (bottom) with lithium and metal occupying their ideal Wyckoff positions [123,130,136,147,148,151]. For all three space groups, edge sharing octahedral  $\text{LiM}_2$  layers alternate with edge sharing octahedral Li layers. The difference in space groups and their associated symmetries can in part be ascribed to stacking of the  $\text{LiM}_2$  layers, with  $R\bar{3}m$  as the highest in symmetry. The space group assignments of some  $\text{Li}_2\text{MO}_3$  systems has been controversial. For example,  $\text{Li}_2\text{MnO}_3$  was first refined to be  $C2/c$ , but later found to be  $C2/m$  on the basis of electron diffraction and transmission electron microscopy [145,146].

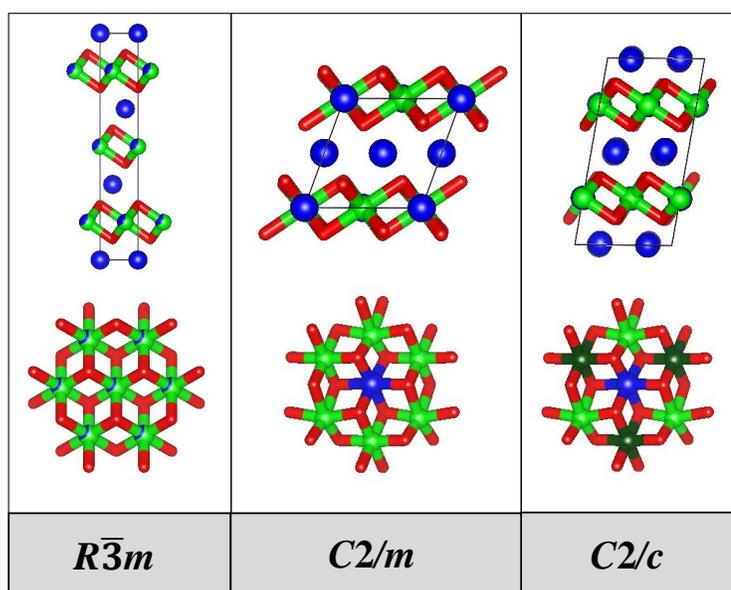

Figure 6.2:  $\text{Li}_2\text{MO}_3$   $R\bar{3}m$ ,  $C2/m$ , and  $C2/c$  unit cells illustrated down the b-axis (top) and corresponding portion of the Li-M layer representing a single hexagonal configuration (bottom) with lithium and metal occupying their ideal Wyckoff positions (lithium and metal labeled blue and green respectively). For  $C2/c$  there are two unique atomic positions to describe M sites within the  $\text{LiM}_2$  layer, represented as the two different shades of green.

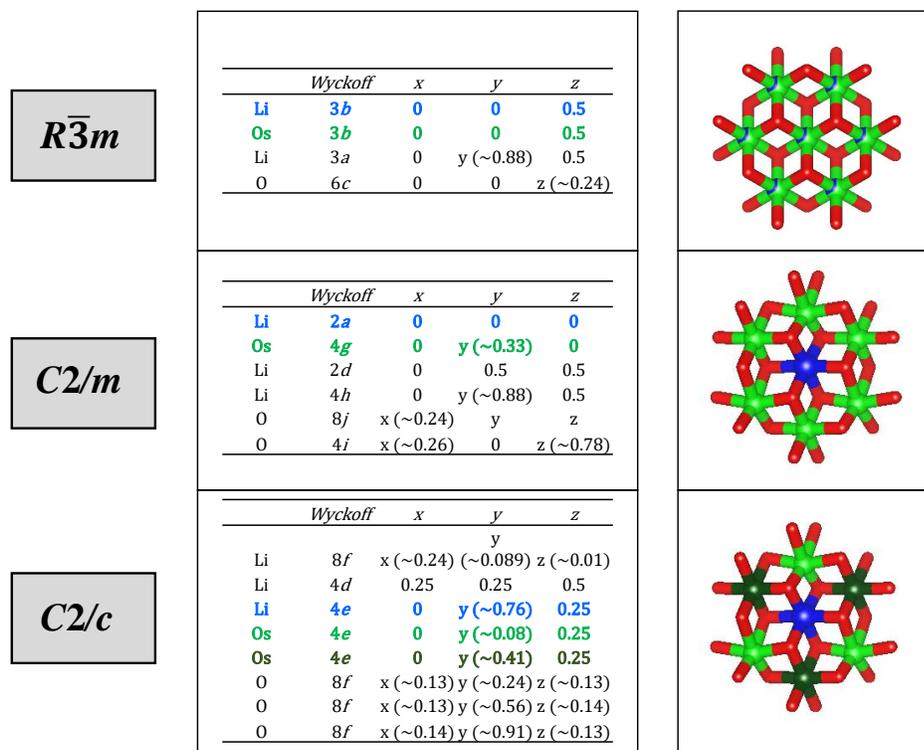

Figure 6.3:  $A_2MO_3$   $R\bar{3}m$ ,  $C2/m$ , and  $C2/c$  space groups and corresponding Wyck-off positions.

Another example is  $Li_2MoO_3$ , which was reported as both  $C2/c$  and  $R\bar{3}m$  [123,147]. When comparing literature on polycrystalline  $Li_2IrO_3$  synthesized under standard solid state conditions, discrepancies in  $C2/c$  and  $C2/m$  space groups exist. Recent work supports the higher symmetry  $C2/m$  as the appropriate space group for polycrystalline  $Li_2IrO_3$  [136, 148, 151]. The powder X-ray diffraction pattern of  $Li_2OsO_3$  is shown in Figure 6.4 (top black line).

At first glance, the X-ray pattern pointed to a more symmetric space group,  $R\bar{3}m$ , however, close examination of the pattern showed weak and broad diffraction

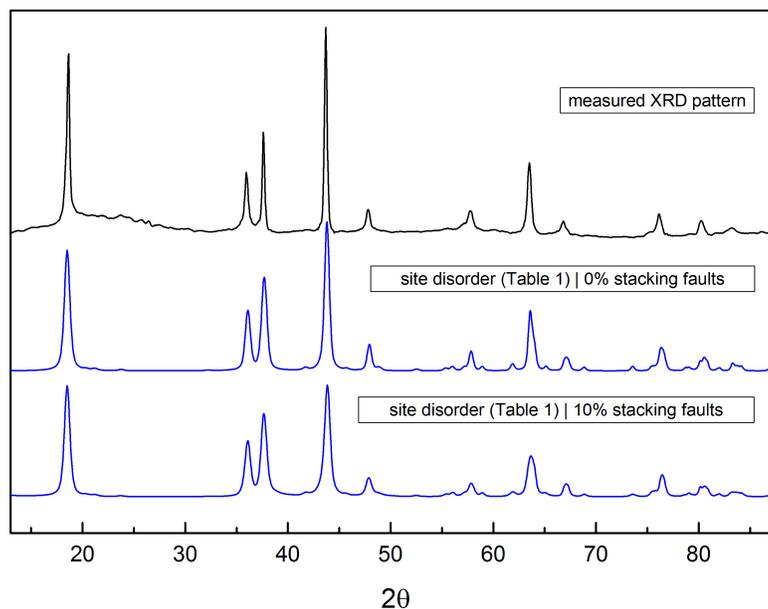

Figure 6.4: A comparison of the measured XRD pattern (top black line) ( $\lambda = 1.514$  Angstroms), along with 43% site disorder (Table 1) | 0% stacking fault and 43% site disorder (Table 1) | 10% stacking fault simulated DIFFaX patterns (blue lines).

peaks in the  $2\theta$  region of  $19^\circ$  to  $33^\circ$ . It is known that for both  $C2/m$  and  $C2/c$  systems, with no Li-M site exchange within the  $\text{LiM}_2$  layers, sharp peaks exist within the  $19^\circ$  to  $33^\circ$  range. However, introducing Li-M site exchange within the  $\text{LiM}_2$  layers decreases the relative intensities of these peaks, leading to virtually no peak presence at approximately 30% Li-M site exchange [149]. Such a reduction in diffraction peak intensity is also found for  $(hk0)$  reflections past  $38^\circ$  [149]. Disorder among Li-M sites is commonly reported for honeycomb layered metal oxides since all corresponding crystallographic sites are octahedral and similar in size [123, 128,

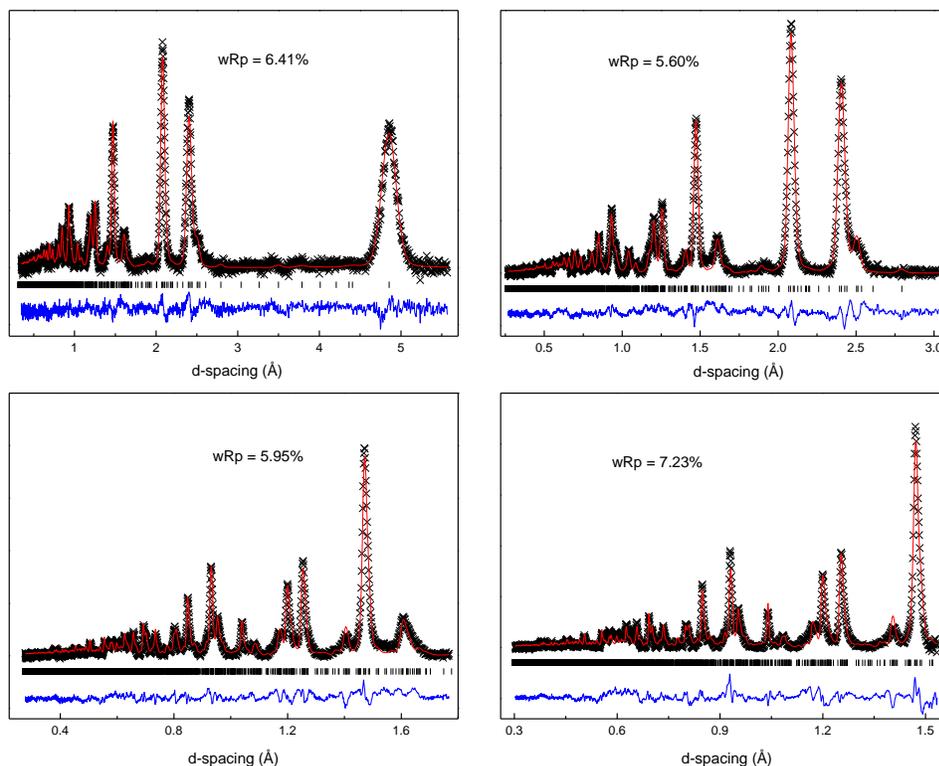

Figure 6.5: Rietveld refinement of TOF Neutron (Oak Ridge NOMAD BL-1B) diffraction data. The collected data (black cross), Rietveld refinement (red line), and difference (blue line) are presented for all four collected banks. Resulting cumulative  $wR_p = 6.4\%$ .

130, 136, 137, 145–147]. The presence of stacking faults associated with a shift between successive  $\text{LiM}_2$  layers will cause the peaks in the region from  $19^\circ$  to  $33^\circ$  to further broaden asymmetrically [126–128, 137, 149]. Thus, with the existence of Li-M site disorder and stacking faults, it is difficult to distinguish between the corresponding space groups using powder X-ray diffraction. The x-ray scattering length for lithium and oxygen are also small due to their low  $Z$ . Because of the

neutron scattering lengths of lithium, osmium, and oxygen, neutron diffraction is ideal to characterize the  $\text{Li}_2\text{OsO}_3$  structure.

To determine the crystal structure, Rietveld refinements were performed on room temperature neutron diffraction data using the GSAS program (Figure 6.5) [152, 153]. The current synthesis procedure restricted diffraction measurements to the Oak Ridge NOMAD TOF Neutron beamline, which is well-suited for small sample sizes. A pseudo-Voigt peak shape profile was chosen and parameters refined to obtain the best fit to the collected data. The space group was refined to be  $C2/c$ , with lattice dimensions  $a = 5.09 \text{ \AA}$ ,  $b = 8.81 \text{ \AA}$ ,  $c = 9.83 \text{ \AA}$ , and  $\beta = 99.3^\circ$ . Rietveld refinements for all collected banks show cumulative  $wR_p = 6.40\%$ . The atomic coordinates, occupancies, and isotropic displacement parameters are represented in Table 6.1.

Interatomic distances and angles are given in Table 6.2. No osmium is detected in the lithium-only layers. For  $C2/c$  there are three unique atomic positions to describe the Li and Os sites within the  $\text{LiOs}_2$  layer. Shown in Table 6.1, corresponding sites are labeled as Li/Os 3, 4, and 5. If no Li-Os site disorder existed within the  $\text{LiOs}_2$  layer, only Li3, Os4, and Os5 would exist (each with an occupancy of 1), with Os4 and Os5 sites describing the honeycomb rings. As shown from Table 6.1 occupancies, a large percentage of Li-Os site disorder exists within the  $\text{LiOs}_2$  layer. For each of the three respective crystallographic sites, an average of 43% is occupied by lithium. The stoichiometry derived from occupancy refinements of Li, Os, and O is  $\text{Li}_{2.15(3)}\text{Os}_{0.85(3)}\text{O}_3$  suggesting an average osmium oxidation state of  $4.5 \pm 0.1$ . It is important to note that oxygen occupancy refinements indicate

that the oxygen sites are fully occupied and no detectable vacancies are observed. Though 2:1 stoichiometric amounts of Li:Os were used in the synthesis, the refined stoichiometric ratio is considered reasonable as the presence of a small amount of osmium impurity is formed during the synthesis and was removed by heating the sample in air at 300 °C as  $\text{OsO}_4$  through sublimation.

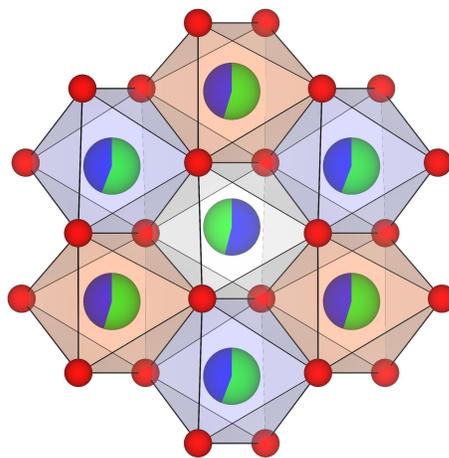

Figure 6.6: Illustration of the  $C2/c$  honeycomb ring with lithium and osmium sites labeled according to Table 6.1 with Os3/Li3, Os4/Li4, and Os5/Li5 octahedral sites as grey, purple, and orange (osmium and lithium labeled green and blue respectively).

Stacking faults were modeled using the FAULTS program [154] and the description of the model and analogous XRD patterns are discussed in Chapter 6. The FAULTS program requires the cell axes to be defined with the  $c$ -axis perpendicular to the fault direction. For a monoclinic space group a new idealized unit cell for each individual layer must therefore be established. The new hexagonal unit cell was defined as  $a_{hex}=a_{(C2/c)}$  and  $c_{hex}=[(c_{(C2/c)}\cos(\beta_{(C2/c)}-90))/2](z)$ , with  $z$  as

the number of hexagonal layers used for the model. Division of 2 is based on the number of repeating Li-LiM<sub>2</sub> layers within  $C2/c$  unit cell. Layer extension in a- and b- direction was set to infinite. The single layer used in DIFFaX and Li-LiOs<sub>2</sub>  $C2/c$  layer are illustrated in Figure 6.7.

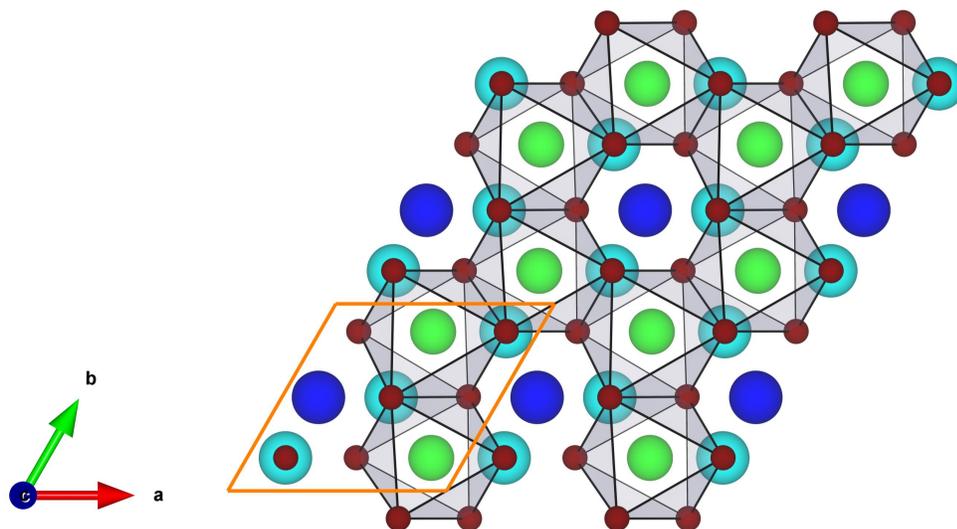

Figure 6.7: Illustration of the FAULTS single layer down the  $c$ -axis for Li<sub>2</sub>OsO<sub>3</sub> with no Li-Os site disorder. Here, Osmium and oxygen are represented as green and red spheres, respectively. Lithium residing within the honeycomb rings are represented as dark blue spheres and lithium beneath the honeycomb layers as lighter blue spheres.

To replicate the ideal stacking sequence of Li<sub>2</sub>OsO<sub>3</sub> ( $C2/c$ ), layer sequencing was characterized by  $[1/3,0,1/z]$  transition vector ( $R_1$ ). To replicate stacking fault contribution, transition vectors  $[0,1/3,1/z]$  and  $[2/3,0,1/z]$  ( $R_2$  and  $R_3$ ) were incorporated. Probabilities were assigned to each of the three transition vectors, with  $\alpha_1 + \alpha_2 + \alpha_3 = 1$  for each layer. For the latter two transition vectors, there was no

tangible difference in the model when varying the contribution for a given total stacking fault probability. Thus for the models presented, the assumption  $\alpha_2=\alpha_3$  was implemented. Figure 6.8 shows a comparison of the measured XRD pattern (top black line), along with 0% site disorder — 0% stacking fault, 0% site disorder — 30% stacking fault, and 50% site disorder — 0% stacking fault simulated patterns (blue lines) within 17-35  $2\theta$  region. With incorporation of stacking faults, only (002) and (020) peaks within 17 – 35  $2\theta$  range do not broaden (Figure 6.9).

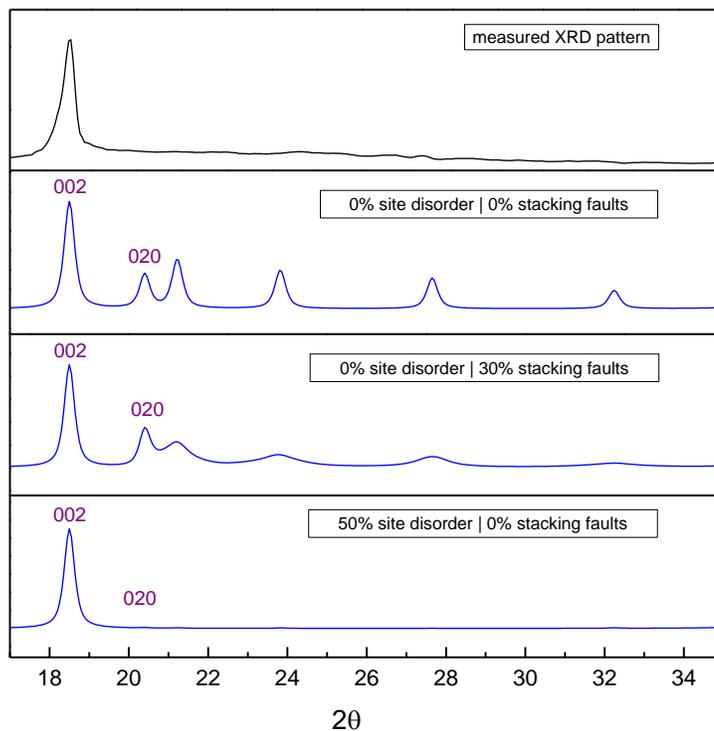

Figure 6.8: Measured XRD-pattern (black) and simulated FAULTS patterns of stacking faulted without site disorder and 50% site disorder of  $\text{Li}_2\text{OsO}_3$  within 17 – 35  $2\theta$  range.

Similar observations for other DIFFaX modeled  $\text{Li}_2\text{MO}_3$  systems exist [126,128,137,155–157]. Calculated XRD patterns with site disorder equivalent to Table 6.1 without and with 10% stacking faults are shown in Figure 6.4. The absence of the (020) peak is therefore attributed to Li-Os site disorder within the  $\text{LiOs}_2$  layers. From the discussion presented, the absence of the (020) peak can only be attributed to Li-Os site disorder within the  $\text{LiOs}_2$  layers and not from stacking faults, consistent with the neutron refinement. As shown in Figure 6.4, the measured XRD pattern is compared to simulated DIFFaX patterns with site disorder representing Table 6.1 refined Wyckoff site occupancies with and without 10% stacking faults (blue lines).

XAS measurements at the Os  $L_{2,3}$  absorption edges ( $2p_{\frac{1}{2},\frac{3}{2}} \rightarrow 5d$  resonant excitation) were used to provide an additional estimate of Os valence (Figure 6.10). The enhanced X-ray absorption above the leading edge (“white line”) is a result of large density of empty 5d states near the Fermi level. This peak grows in intensity and shifts to higher energy with increasing Os oxidation state. Interpolating the XAS peak position in the honeycomb sample onto those of the reference compounds yields an oxidation state of  $+4.7 \pm 0.2$ , within errors of results from structure refinements.

The ratio of  $L_3$  to  $L_2$  white line intensity, also known as the isotropic branching ratio (BR), provides a measure of the relevance of SOC interactions in the 5d band [158,159]. In the absence of sizable SOC interactions, the isotropic branching ratio equals 2 reflecting the different occupancies of the core levels at  $L_3$  and  $L_2$  edges. We measured  $\text{BR}=2.9(1)$  which significantly differs from the statistical

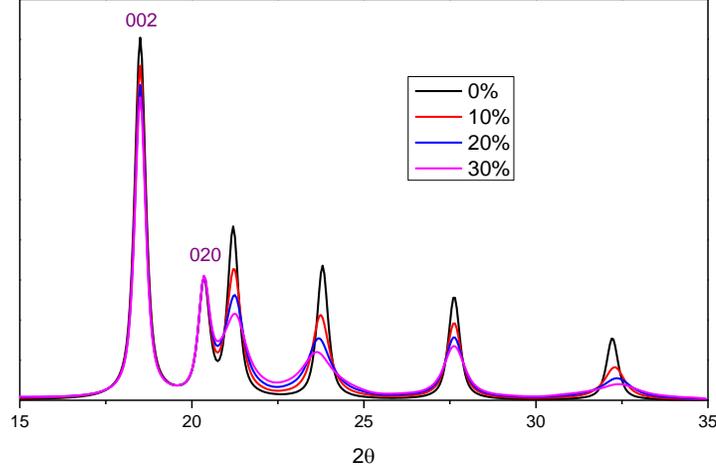

Figure 6.9: Simulated FAULTS XRD patterns with 0% - 30% stacking faults and no site disorder within 15 – 35  $2\theta$  range .

value of 2 and indicates that SOC interactions need to be included in order to describe the 5d electronic structure of this compound.

### 6.3.2 Thermodynamic and Transport Properties

Temperature dependent resistivity and Seebeck measurements from 300 – 600 Kelvin are shown in Figure 6.11. The gap energy ( $E_g$ ) for the sample was extracted using  $\rho = \rho_0 \exp(E_g/2k_B T)$  with  $E_g = 220$  meV and 266 meV obtained from low- and high-temperature transport measurements respectively, thus indicating a small band gap insulator (Figure 6.11 - bottom).

The magnetic susceptibility,  $\chi_{dc}$ , for  $H = 0.5$  T (Figure 6.12) suggests the

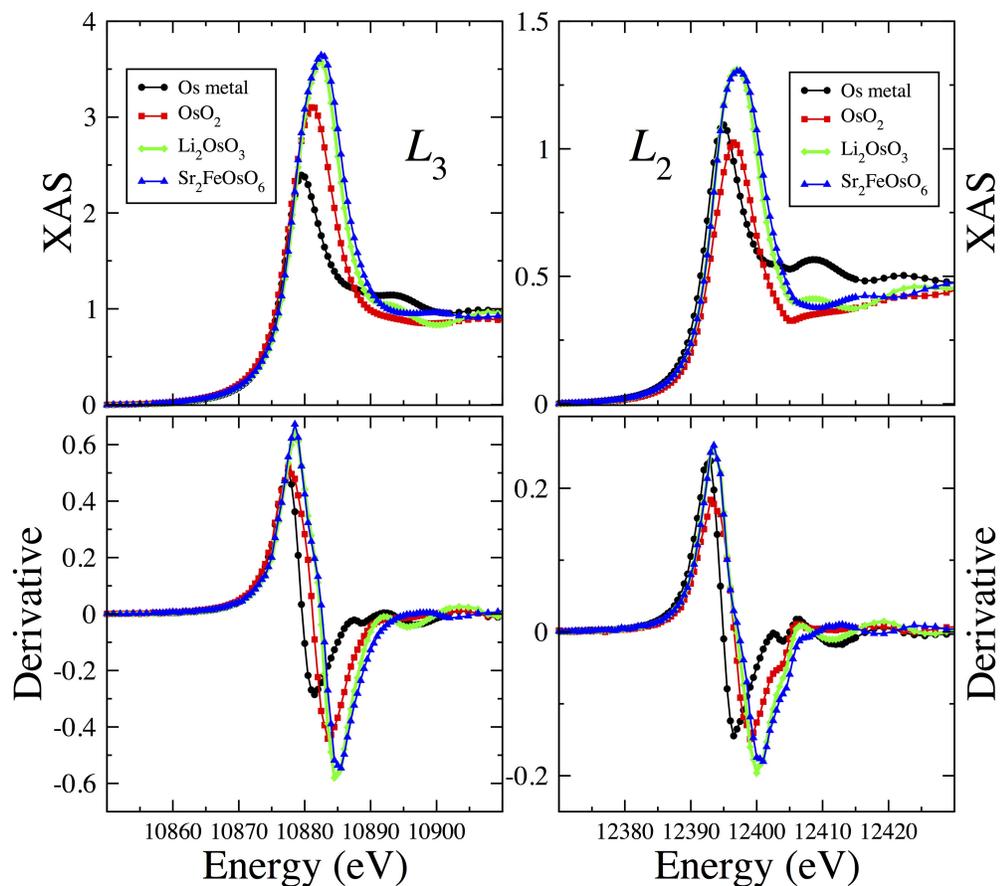

Figure 6.10: XAS measurements at the Os  $L_{2,3}$  absorption edges on  $\text{Li}_{2.15}\text{Os}_{0.85}\text{O}_3$  and three reference compounds with known oxidation state.

combined effects of Curie-Weiss as well as van Vleck temperature independent paramagnetism over the entire measurement range above 2 K. Within this assumption, we varied the magnitude of the van Vleck term,  $\chi_{VV}$ , to produce a pure Curie-Weiss contribution. We found that subtracting  $\chi_{VV} = 0.00135$  emu/mole from the measured  $\chi(T)$  produces the straightest  $1/\chi(T)$ , resulting in a good fit to the Curie-Weiss form,  $\chi = C/(T-\theta)$ , where  $C$  is the Curie constant and,  $\theta$  is

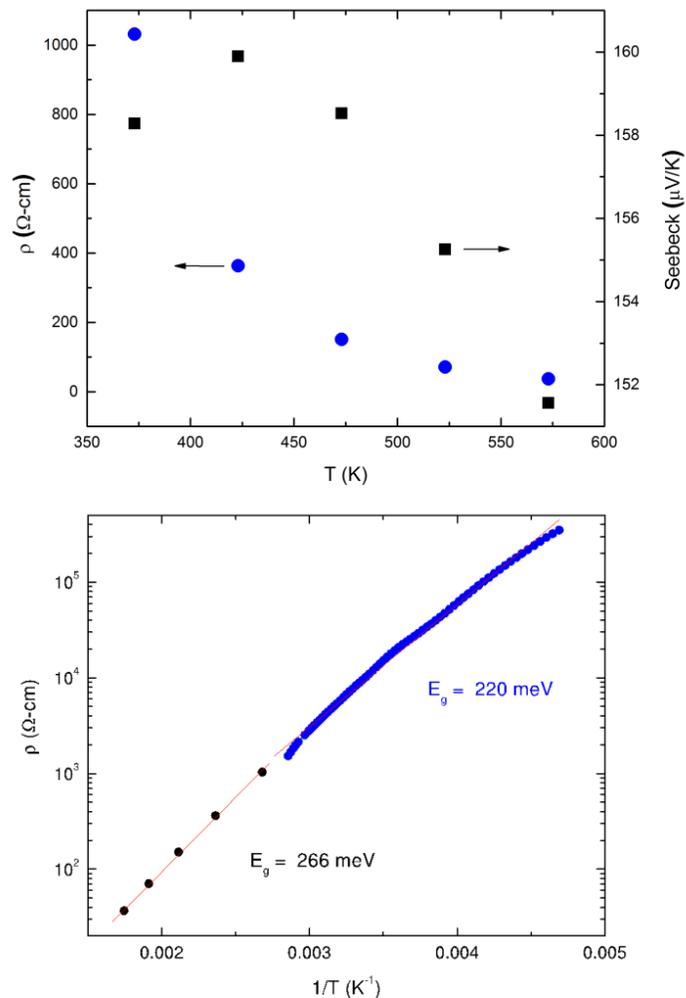

Figure 6.11: Top: High temperature resistivity and Seebeck coefficient data of  $\text{Li}_{2.15}\text{Os}_{0.85}\text{O}_3$  sample from 350 to 600 K. Bottom: Resistivity versus temperature for  $\text{Li}_{2.15}\text{Os}_{0.85}\text{O}_3$  in the range 200 – 600 K versus inverse temperature. The low and high temperature measurements were performed in different apparatuses on samples from the same growth run. To assure continuity at  $T = 300$  K, the data have been rescaled for the low temperature measurement due to its greater uncertainty in the geometric factor.

the Weiss constant.

Fitting the data between 50 and 200 K yields a Weiss constant of  $\theta = -11.5$  K and a finite effective moment  $\mu_{eff} = 0.85 \mu_B$ , significantly greater than expected for the  $J_{eff} = 0$  state of Os(+4). Given the above XAS and neutron scattering refinement results showing that the average Os valence is 4.7, however, an alternate ionic scenario is for 70% of the Os ions to be in the +5 state ( $J_{eff} = \frac{3}{2}$ ) and 30% in the +4 state ( $J_{eff} = 0$ ). This analysis yields  $\mu_{eff} = 1.01\mu_B$  ( $\theta = -11.8$  K) for the magnetic (+5) ions, which is now significantly less than the expected moment.

We discuss possible sources of this discrepancy below. These  $\chi_{dc}$  data were augmented with ac-susceptibility ( $\chi_{ac}$ ) data down to 0.1 K, which were calibrated to the  $\chi_{dc}$  data in the overlapping temperature range 2.0 – 2.5 K. A peak in  $\chi_{ac}$  is observed at 0.5 K, but is rapidly suppressed by magnetic fields far less than 0.1T. Given the usual relationship between  $H$  and T for a g-factor of two, one expects suppression of an antiferromagnetic ordering feature at 0.5 K for  $H$  values an order of magnitude larger than observed. Alternatively, such a cusp in  $\chi_{ac}$  can be attributed to spin glass freezing, a scenario consistent with the high degree of disorder in this spin system. The spins involved in such freezing may not represent the bulk of the Os(+5) spin population, as we argue below.

The existence of a small subset of spins that are interacting at a mean field energy scale of  $k_B T$  for  $T = 0.5$  K, as suggested by the  $\chi_{ac}$  peak, is also supported by  $C(T, H)$ , shown in Figure 6.13.

For semiconductors, the Einstein - Debye theory of specific heat can be applied to model the change in specific heat at low temperatures. The Einstein - Debye

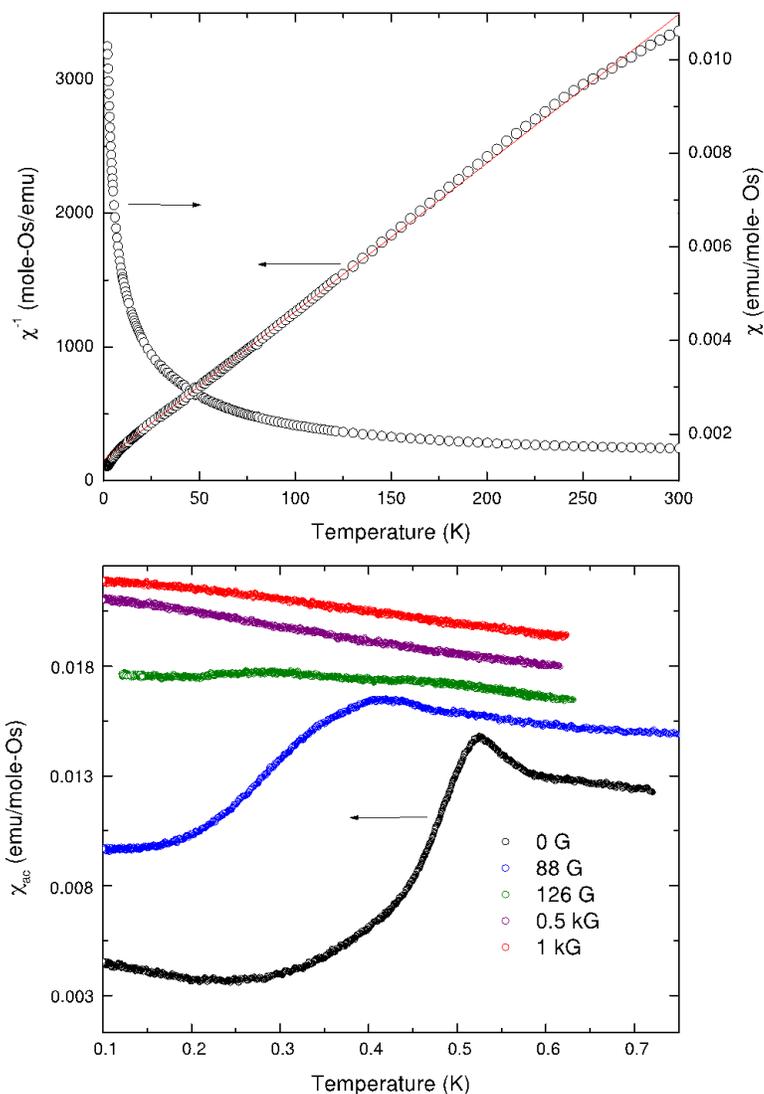

Figure 6.12: Top: DC-Susceptibility  $\text{Li}_{2.15}\text{Os}_{0.85}\text{O}_3$  versus temperature. Also shown is the inverse susceptibility after subtracting a van Vleck term as described in the text. Bottom: ac-susceptibility versus temperature at different values of applied magnetic field. The curves have been offset vertically by 0.0020, 0.0032, 0.0044, and 0.0056 emu for  $H = 88, 126, 500,$  and  $1000$  G respectively, for clarity.

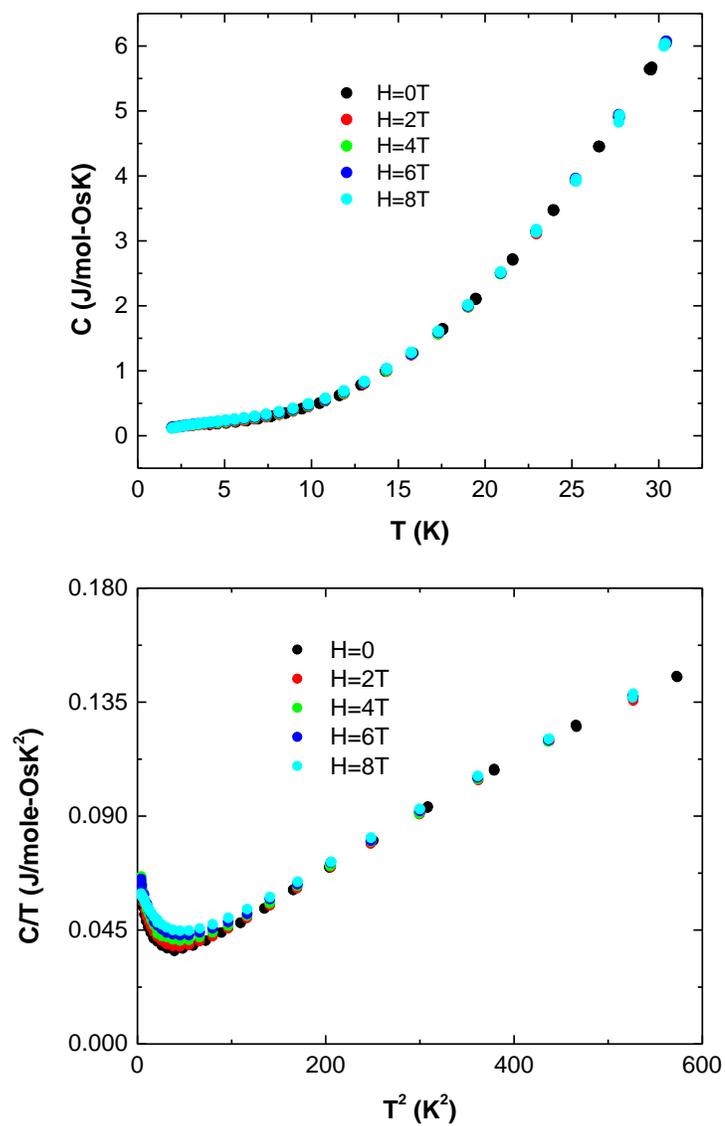

Figure 6.13: The specific heat  $C(T)$  of  $\text{Li}_{2.15}\text{Os}_{0.85}\text{O}_3$  in various applied fields, measured using a Physical Property Measurement System. Bottom: Plotting  $C/T$  vs.  $T^2$  from the Einstein-Debye model should result in a linear correlation if no phase/electronic transition occurs.

theory is calculated theoretically by taking the partial derivative of the internal energy with respect to temperature (discussed in Chapter 2). From the Einstein - Debye equation, the electronic contribution to the specific heat is proportional to  $T$  and the vibrational contribution to the specific heat is proportional to  $T^3$ . For any sort of physical state transition-phase, magnetic ordering, and/or transition to a superconducting state, an increase in the specific heat will be observed at the corresponding transition temperature. Thus, by plotting  $C/T$  versus  $T^2$ , from the Einstein - Debye expression, a linear trend will be observed as long as a physical/electronic transition does not occur within the temperature region. As shown in Figure 6.13,  $C/T$  exhibits an upturn below its minimum at  $T = 6$  K. This upturn is only moderately affected by fields up to 8 T, so we model this as  $C = C_1(T) + C_2(T,H)$ . Here  $C_1$  is a combination of the lattice specific heat and an H-independent electronic contribution and  $C_2$  is a combination of the lattice specific heat and an H-dependent electronic contribution. Taking the difference between  $C(H = 8\text{T})$  and  $C(H = 0)$ , the H-dependent electronic contribution (“spin impurities”) can be shown in terms of a Schottky trend, where  $C_2(T,H=8\text{T})$  resembles a broadened Schottky anomaly (Figure 6.14). Recall, the existence of a small subset of spins suggested by the  $\chi_{ac}$  peak. This observation is also supported by the specific heat. We can fit this contribution to either a single  $J_{eff} = \frac{3}{2}$  ( $g = 1.3$ ) Schottky anomaly or a pair of  $J_{eff} = \frac{1}{2}$  ( $g = 2.6$  and  $7.4$ ) Schottky anomalies with molar concentrations of 4.1% and 9.6% (total for the pair) respectively (Assuming 70% of the spins are magnetic, these fractions become 5.9% and 13.7%). By subtracting  $C(H=8\text{T})$  from  $C_{schottky}$  trends (i.e. subtracting out the contribution

of the “spin impurities”), the resulting lattice specific heat and an H-independent electronic contribution can be plotted as a power plot (Figure 6.14). A resulting power law  $T^{0.63}$  is therefore obtained. Thus, it is not unlikely that the spins undergoing spin-glass-like freezing are the same spins responsible for the Curie-tail susceptibility. We now turn to the  $C_I(T)$  term, which is calculated using the two different Schottky approximations mentioned above and plotted Figure 6.14. We note that, below 8 K,  $C_I(T) \propto T^\alpha$ , where  $\alpha = 0.69$  and  $0.57$  for the  $J_{eff} = \frac{3}{2}$  and  $\frac{1}{2}$  Schottky analyses respectively. Such a sublinear form cannot persist down to the lowest temperatures, and importantly is clearly distinct from the phonon contribution visible above 8 K. At the same time, it appears that, among the 70% of Os ions that are in a +5 state (within an ionic picture) and thus possibly magnetic, less than 15% are accounted for in either susceptibility or field-dependent specific heat. All known spin frustrated systems possess a resulting power law with  $\alpha = 2$ . The only known systems that possess  $\alpha < 1$  are quantum spin liquid candidates [160]. If the sublinear low-T contribution is due to these unaccounted for, but nevertheless magnetic, Os(+5) ions, then they must be in a type of singlet state due to exchange interactions with a strength greater than the Zeeman energy of an 8 Tesla field, but of a type that invalidates the effective moment approximation below room temperature.

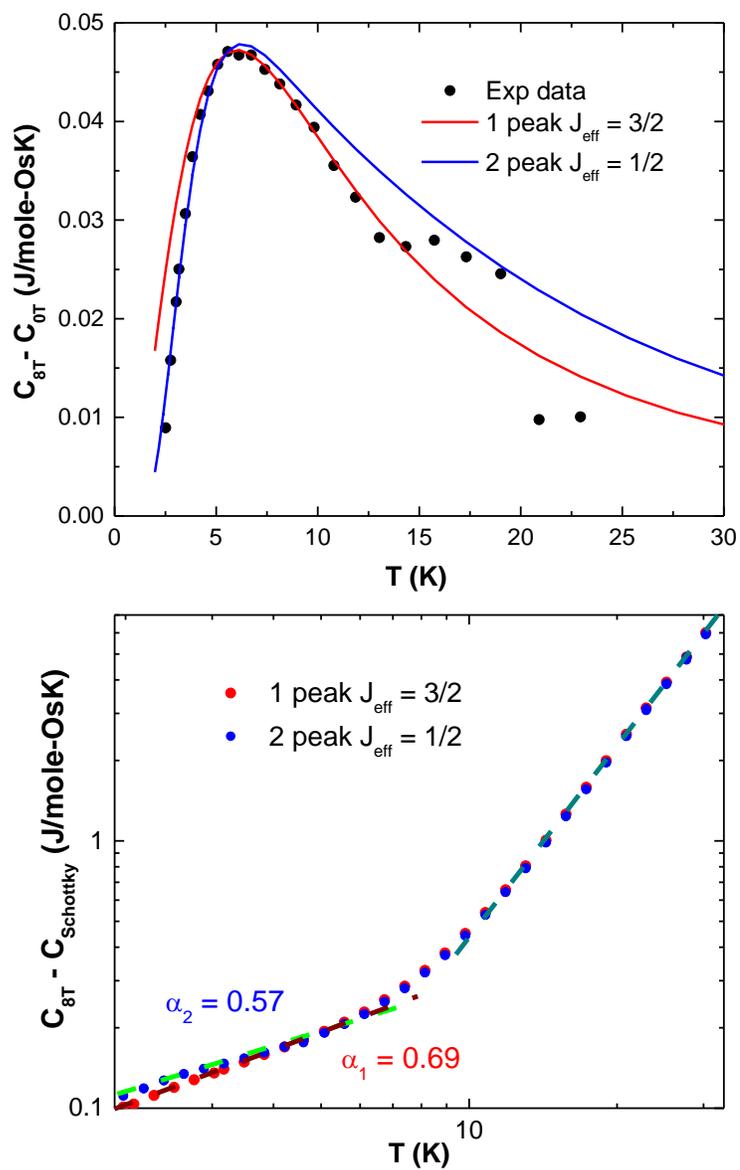

Figure 6.14: Top: Impurity spins modeled with a Schottky anomaly. Bottom: Specific heat after removing the impurity contribution.

### 6.3.3 Electronic Structure

Early model treatments of 5d oxides on honeycomb lattices built on the ionic description of crystal field splitting, additionally with strong SOC among orbitals, focused attention on the  $t_{2g}$  subshell  $J_{eff} = \frac{1}{2}$  and  $\frac{3}{2}$  subspaces. The relevant energy scales of individual bandwidth  $W$ , Hubbard  $U$ , Hund's  $J_H$ , and SOC strength  $\xi$ , all lie in the 0.5-1.5 eV range, and studies of the electronic structure and especially the exchange coupling have concluded that the ionic picture provides a challenging starting point at best. The electronic structure of octahedral osmates is complicated by several features. First, the active  $t_{2g}$  orbitals are strongly hybridized with the oxygen 2p orbitals, resulting in strongly coupled Os 5d – O 2p states as the fundamental chemical unit. Osmates in the  $\text{Ba}_2\text{NaOsO}_6$  family, for example, have half of the spin density residing on the O octahedron [161, 162]. Iridates behave similarly, leading to their characterization as *molecular orbital compounds*, which can lead to longer range exchange coupling parameters compared to more localized moments [163]. Second, SOC also affects the electronic structure, creating both single-ion as well as exchange anisotropy, the relative effects of which are difficult to disentangle. Third, the distortion from ideal rhombohedral symmetry introduces new lower symmetry Fourier components of the potential that causes band anti-crossings. These in turn result in very narrow, 0.3 eV, individual bandwidths and the likelihood of small gaps, as shown below.

Several theoretical studies of honeycomb iridates have concluded that magnetic interactions beyond the Heisenberg-Kitaev model are important, suggesting a more

itinerant picture of the electronic structure [164–170]. Many of the general findings for iridates carry over to osmates. Our compound presents the additional complication of Os possessing a nominal valence of +4.7, so one must consider a mixture of  $d^3$  with  $d^4$  ions. The ionic picture of  $d^4$  begins with a non-magnetic  $J_{eff} = 0$  ion and for  $d^3$  the ionic value is  $J_{eff} = \frac{3}{2}$ , and the insulating nature suggests these different ionic states reside on distinct lattice sites, as opposed to the intermediate valence picture. In this ionic picture, the measured  $\mu_{eff} = 0.85\mu_B$  is challenging to account for, as mentioned above, which leads us to consider the general question of moment formation in nearly itinerant systems.

In an effort to reconcile the valence state measurements with the magnetothermal measurements, we have applied density functional theory (DFT) methods including SOC, correlation effects, and a fixed atomic spin moment method in our study of  $\text{Li}_2\text{OsO}_3$  (see Methods for the description) [171–176]. Without magnetism, SOC is strong enough to provide a pseudogap but no gap, within the Os  $t_{2g}$  bands. This SOC-driven separation is compromised by crystal subfield splittings, bandwidth effects, and anti-crossings arising from structural distortion away from rhombohedral symmetry leaving two inequivalent Os sites. The resulting band structure (not shown) is that of a very narrow, essentially zero (indirect) gap semiconductor. Due to the molecular orbital nature of the  $t_{2g}$  band complex, intra-atomic repulsion effects as treated by the Hubbard U repulsion are ineffective in opening a gap, for reasonable values of U (2 eV or less). Antiferromagnetic order tends to encourage gap opening, producing Os moments of  $0.3 \mu_B$ .

To include in the modeling the effect of the observed Os moment, we have

adopted the constrained atomic moment method as implemented in the *abinit* code [171]. This method proceeds not by specifying a value for  $U$  for the Os 5d orbitals, but by fixing the spin moment by applying an intra-atomic Zeeman field determined self-consistently; both magnitude and direction can be specified separately for any atom. Magnitudes of  $0.8 \mu_B$  and  $0.5 \mu_B$  have been studied; the latter value represents the ordered component expected of a  $0.8 \mu_B$  local (C-W) moment. Bandgaps of 0.25 eV and larger were obtained, depending weakly on the imposed moment but strongly on the magnetic alignment (the larger ones were for AFM order). The resulting orbital moments are minor, only a few hundredths of  $1 \mu_B$ , independent of the chosen direction of spin. These results do not fit that of a Mott insulator: there is no robust local moment, and Hubbard  $U$  is not needed to open a gap and has little effect on the size of the gap. Thus our model rationalizes the observations of a narrow transport gap and small magnetic moment in  $\text{Li}_{2.15}\text{Os}_{0.85}\text{O}_3$ .

Due to intermixing of Li on the Os honeycomb lattice, we have made an initial study of the effect of intermixing, by replacing 25% of the Os sublattice by Li while keeping the Li sublattice intact. The Os moments are fixed with magnitude  $0.8 \mu_B$  and oriented along separate (111) axes to mimic disordered moments. The resulting band structure, shown in Figure 6.15, illustrates the flat individual bands that arise, and that a very small gap exists or is imminent, depending on details of the calculations. The bands are not significantly different in appearance from those of  $\text{Li}_2\text{OsO}_3$ .

We now focus on the effect of Li substitution on the remaining Os ions. This

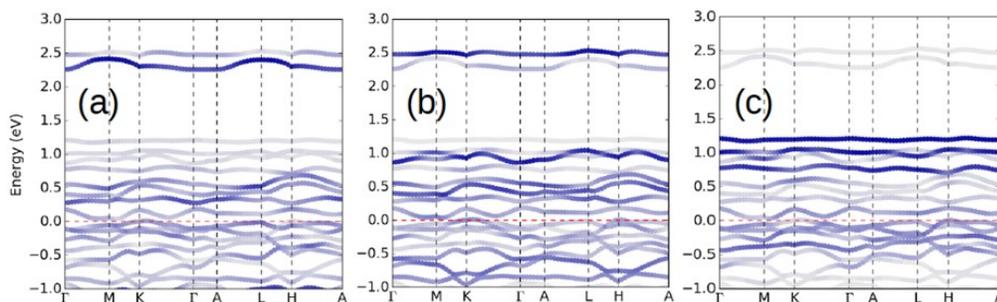

Figure 6.15: Plot of bands in the Os  $t_{2g}$  region of 25% Li-substituted  $\text{Li}_2\text{OsO}_3$  on the Os honeycomb sublattice, with energy zero (horizontal red dashed line) denoting the gap region. The fatbands plots emphasize the Os 5d character on (a) the Os[0] site with no Li neighbor, (b) the Os[1] site with one Li neighbor, and (c) the Os[2] site with two Li neighbors. While Os[0] and Os[1] show some differences, Os[2] is qualitatively different.

25% replacement results in three Os sites, denoted by Os[j] which has  $j$  Li neighbors,  $j = 0, 1$ , or  $2$ . The formal valences of Os in this  $\text{Li}_2(\text{Li}_{1/4}\text{Os}_{3/4})\text{O}_3$  structure should average to  $5+$ . The periodicity leaves Os[0]-Os[1] chains and comparatively isolated Os[2] ions, which in addition to two Li neighbors the Os neighbor is at a long Os-Os separation. The spectral distribution of Os[2] in Figure 6.15 is substantially different from the other two, more representative of a lower oxidation state. While simple electron count indicates that Li substitution must oxidize some Os ions, having two Li neighbors strongly affects the formal valence of the Os ion.

This modeling illustrates that the Os valence is sensitive not only to the total charge available, but also to the local environment. Different valence states carry different moments, and sensitivity to the local environment suggests that variation of exchange constants promotes a frustration of magnetic order. Note in Figure 6.15 that the spectral distributions of 5d weight are significantly different for Os[0]

and Os[1], while that of Os[2] is less weight in the occupied bands. This implication then is that of one Os(4+) ions and two Os(5+) ion, with an average valence of 4.67 consistent with spectroscopic evidence on our samples. More of a specific nature cannot be concluded because the Os moments were constrained (to be equal), whereas those of different valence states would not be equal.

## 6.4 Summary

We have presented the first example of Os on a honeycomb structure,  $\text{Li}_{2.15(3)}\text{Os}_{0.85(3)}\text{O}_3$ , and have characterized it with atomic, structural, and magneto-thermal probes. The Os ions have an average valence state of +4.7 and large site disorder exists in the honeycomb layers. This compound is a narrow band gap semiconductor. The magnetic susceptibility and specific heat present a picture in which the effective Os moment is reduced to a value well below that expected from the valence-state measurements, which suggests that the valence electrons are on the verge of itineracy, a conclusion supported by our density functional theory calculations. These results strongly suggest that spin orbit coupling of Os is playing an important role in the collective electronic behavior of this honeycomb system, and that further studies of osmates on frustrating lattices are warranted.

## 6.5 Methods

### 6.5.1 Synthesis and Structure Characterization

Stoichiometric amounts of  $\text{Li}_2\text{CO}_3$  and  $\text{OsO}_2$  (synthesized from osmium metal - see below) were intimately ground, pressed into a pellet, loaded into an alumina crucible, and fired in a tube furnace at 700 C under Argon flow. Firing was repeated to 850 C with 50 C increments, grinding the sample before each firing. Each firing was performed under argon flow. The  $\text{OsO}_2$  sample was synthesized by first placing a known amount thin layer of osmium metal in an alumina crucible. The crucible was then placed in an atmosphere controlled quartz tube furnace setup. Argon gas flow was introduced for approximately 20 minutes. The quartz tube setup was then sealed and vacuum out the argon atmosphere to  $\sim 0.05$  MPa below atmospheric pressure. A stoichiometric amount of  $\text{O}_2$  gas was introduced based on the relative pressure change. The resulting tube furnace setup was then slowly fired to  $\sim 600$  C for  $\sim 3$  hours. Phase analysis of the powder samples was performed by X-ray diffraction using a Rigaku MiniFlex II diffractometer with  $\text{Cu K}\alpha$  radiation and a graphite monochromator for the diffracted beam. Time of Flight (TOF) neutron diffraction measurements were collected at ORNL NOMAD BL-1B SNS beamline. X-ray absorption spectroscopy measurements were carried out at beamline 4-ID-D of the Advanced Photon Source at Argonne National Laboratory using a transmission geometry. Reference samples for valence determination included Os metal,  $\text{Os}^{4+}\text{O}_2$  and  $\text{Sr}_2\text{FeOs}^{5+}\text{O}_6$  [177].

### 6.5.2 Electronic and Thermal Properties

The Seebeck coefficient and electrical conductivity data (350 K – 600 K) were collected on an ULVAC ZEM-3 under a helium atmosphere. Magnetization measurements (2 K - 300 K) were obtained with a Quantum Design MPMS. Resistivity,  $\rho(T)$ , (200 K - 350 K) and specific heat,  $C(T)$ , data (2 K - 30 K) were obtained using a Quantum Design PPMS. Magnetic ac-susceptibility data down to 0.1 K were obtained in a  $^3\text{He}$ - $^4\text{He}$  dilution refrigerator with thermal contact to the mixing chamber made via a copper wire bundle bonded to the sample with Stycast 1266 epoxy. Data were obtained at 143 Hz and with an excitation current low enough to eliminate heating from the coils.

### 6.5.3 Theoretical Methods

We use the open-source package ABINIT [53] to perform electronic calculations, with the generalized gradient approximation (GGA) [54] for the semilocal exchange-correlation functional and the projector augmented wave method (PAW) [174] for core electrons. A Hubbard U repulsive interaction was applied with magnitude as indicated, Hund's  $J_{\text{H}} = 0.4$  eV was applied, on the Os 5d orbitals [175]. A mesh of 9x5x9 was used for k-sampling and 500 eV for energy cutoff. The constrained atomic spin moment on Os method [176] was used in some calculations to fix moments at or near the observed value. Constraints are managed by the use of Lagrangian multipliers, imposed with constraint parameters; the input parameter  $\lambda = 1.0$  was used [172].

## Chapter 7: Unraveling the Mixed Valence Picture of the Double Perovskites $\text{Ba}_{2-x}\text{La}_x\text{YIrO}_6$

### 7.1 Abstract

The interest in perovskites can be attributed to their wide array of properties, which in turn derives from their compositional and structural flexibility. The framework of the  $\text{A}_2\text{MM}'\text{O}_6$  double perovskite containing  $4d/5d$  elements with strong spin-orbit coupling (SOC) are of interest for the exploration of quantum magnetism. In such systems, the interplay between the electron localizing tendencies of SOC and the delocalizing effects of the large spatial extent of the  $4d/5d$  orbitals has the potential to combine with electronic correlations to produce unusual states. The motivation to study  $\text{Ba}_{2-x}\text{La}_x\text{YIrO}_6$  is twofold: (1) to investigate a mixed  $5d^4/5d^5$  iridate perovskite with noncubic symmetry and with iridium as the sole magnetic ion, and (2) to elucidate the influence of local environment on the magnetism in such systems. As shown by the structural refinements presented,  $a^0a^0a^0$  ( $Fm\bar{3}m$ )  $\rightarrow$   $a^0b^-b^-$  ( $I2/m$ ) octahedral distortion of the  $\text{YO}_6\text{-IrO}_6$  rock-salt framework occurs with increasing  $x$  to account for the incorporation of smaller  $\text{La}^{3+}$  radii. From the magnetic susceptibility measurements, deviations from the proposed mixed valence picture are observed, not only for  $x = 0.2$ , but also on approaching  $x = 0.8$ . For  $x = 0.2$ ,  $\chi_{\text{MV}}$  is larger than found for  $x = 0$ .

Publication based on this chapter:

## 7.2 Introduction

The prevalence of perovskites can be elucidated by the compositional and structural flexibility of the corresponding structure. Because of this inherent flexibility, an array of properties have been reported, with numerous examples where substitution of one or more of the cations can considerably impact structure and properties [178–184]. The double perovskite  $A_2MM'O_6$  structure can be described as a close packed  $AO_3$  arrangement with  $\frac{1}{4}$  of the octahedral sites filled with M/M' metals, forming a network of corner shared  $MO_6$ -M'O<sub>6</sub> octahedra with A cations residing in 12-coordinated sites (Figure 7.1).

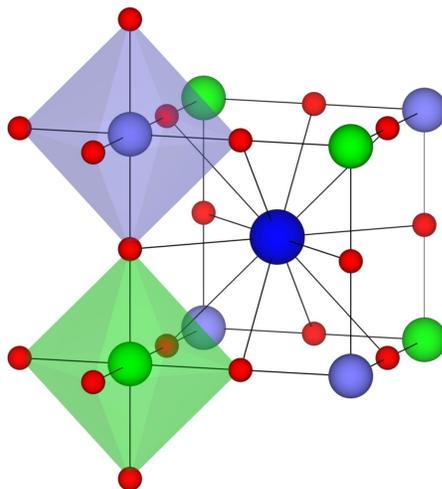

Figure 7.1: The ideal cubic  $A_2MM'O_6$  double perovskite with blue, green/purple, and red representing A-site, M/M'- site, and oxygen, respectively.

Depending on the relative charge, size, and electronegativity differences, the M-site arrangement can be disordered or ordered with possible octahedral distortions

throughout the  $\text{MO}_6\text{-M}'\text{O}_6$  octahedral lattice [178–181,185]. The framework of the  $\text{A}_2\text{MM}'\text{O}_6$  double perovskite containing  $4d/5d$  elements with strong spin-orbit coupling (SOC) are of interest for the exploration of exotic states [182,183,186–189]. Effects due to crystal field, SOC, and electronic correlations can have a strong influence on the electronic states. Of recent interest for topological materials are perovskites where SOC is large enough to influence the electronic band structure. Iridates are the most widely studied perovskites with Iridium frequently in a 4+ oxidation ( $5d^5$ ) state [187,190,191], resulting in a  $s = \frac{1}{2}$  Kramers doublet. Systems with such  $5d^5$  ground states have been predicted to possess anisotropic exchange interactions, a key ingredient of the Kitaev model of quantum spin liquid [192]. In contrast,  $5d^4$  iridates should yield a nonmagnetic ground state with total angular momentum  $J = 0$  and a higher energy triplet which gives rise to van Vleck paramagnetism [193]. Thus,  $\text{Ba}_2\text{YIrO}_6$  is expected to be nonmagnetic. The observed small magnetic moment of  $\text{Ba}_2\text{YIrO}_6$  advocates a non-magnetic state with impurity spins [194–196]. Recent work by Kataev et al, has verified that the magnetism of  $\text{Ba}_2\text{YIrO}_6$  is solely due to a few percent of  $\text{Ir}^{4+}$  and  $\text{Ir}^{6+}$  magnetic defects while the regular  $\text{Ir}^{5+}$  sites remain nonmagnetic, thus confirming the existence of a non-magnetic  $5d^4$  ground state [186]. There are a few reports that endorse the influence of noncubic symmetry on the magnetism of  $5d^4$  iridate perovskites [197,198]. The argument of local environment influencing the SOC, however, is unclear as the spin-orbit Hamiltonian is defined by the fixed term  $(1/r)(\delta V/\delta r)$ , with  $V$  as the nuclear Coulombic potential and  $r$  representing the radial position of the electron. Recent work by Khaliullin speculate  $J_{eff} \neq 0$  in  $5d^4$  iridates can be achieved if the

superexchange (SE) interaction energy is on the order of the SOC [193]. The SOC for  $\text{Ir}^{5+}$  is 540 meV [199]. To our knowledge,  $5d^4$  iridates with SE large enough to overpower such a large SOC has not been observed. The motivation to study  $\text{Ba}_{2-x}\text{La}_x\text{YIrO}_6$  is twofold: (1) to investigate a mixed  $5d^4/5d^5$  iridate perovskite with noncubic symmetry and with iridium as the only magnetic ion, and (2) to elucidate the influence of local environment on the magnetism in such systems. As shown by the structural refinements presented,  $a^0a^0a^0$  ( $Fm\bar{3}m$ )  $\rightarrow$   $a^0b^-b^-$  ( $I2/m$ ) octahedral distortion of the  $\text{YO}_6\text{-IrO}_6$  rock-salt framework occurs with increasing  $x$  to account for the incorporation of smaller  $\text{La}^{3+}$  radii. From the magnetic susceptibility measurements, deviations from the proposed mixed valence picture are observed, not only for  $x = 0.2$ , but also on approaching  $x = 0.8$ . For  $x = 0.2$ ,  $\chi_{VV}$  is larger than found for  $x = 0$ .

### 7.3 Experimental

Stoichiometric amounts of  $\text{BaCO}_3$ ,  $\text{IrO}_2$ ,  $\text{La}_2\text{O}_3$ , and  $\text{Y}_2\text{O}_3$  were intimately ground, pressed into a pellet, loaded onto an alumina crucible, and fired in air at 900 C for 6 hours and then at 1200-1250 C, 12 hour firings each with intermediate grindings. Both  $\text{La}_2\text{O}_3$  and  $\text{Y}_2\text{O}_3$  were preheated at 800 C for 12 hrs. X-ray diffraction (XRD) were collected using a Rigaku MiniFlex II diffractometer with  $\text{Cu } K_\alpha$  radiation and a graphite monochromator for the diffracted beam. The samples were loaded onto an oriented Si single-crystal sample holder (MTI Corporation). Diffraction patterns were collected with a fixed-time scan rate of  $0.02^\circ \text{ step}^{-1}$

and 4.0 s  $\text{step}^{-1}$  from 10 to  $110^\circ 2\theta$ . Time of Flight (TOF) neutron diffraction measurements were collected at Oak Ridge National Laboratory POWGEN BL-11A SNS beamline. The Seebeck coefficient and electrical conductivity data (350 K – 600 K) were collected on an ULVAC ZEM-3 under a helium atmosphere. Magnetization measurements (2K - 300 K) were obtained with a Quantum Design MPMS. Resistivity,  $\rho(T)$ , (200K - 350 K) were obtained using a Quantum Design PPMS.

## 7.4 Results

### 7.4.1 Structure

A combination of powder XRD and TOF neutron diffraction were used establish the most appropriate space group for each  $\text{Ba}_{2-x}\text{La}_x\text{YIrO}_6$  and to refine atomic structures for  $x=0$  and  $x=0.6$  samples. Figure 7.2 shows XRD patterns of  $\text{Ba}_{2-x}\text{La}_x\text{YIrO}_6$  ( $0 \leq x \leq 0.6$ ) samples. A small presence of  $\text{La}_2\text{O}_3$  impurity phase exists for  $x \leq 0.6$ . Trace  $\text{Y}_2\text{O}_3$  impurity phase was detected in the diffraction pattern upon magnification for all samples. With increasing  $\text{La}^{3+}$  content  $x$  from 0 to 0.6,  $Fm\bar{3}m \rightarrow I4/m \rightarrow I2/m$  space group transformations occur with  $\text{La}^{3+}$  solubility limit close to  $x=0.6$  (Figure 7.3). The  $\text{A}_2\text{MM}'\text{O}_6$  rock salt M-site ordered double perovskite of  $a^0a^0a^0$  ( $Fm\bar{3}m$ ),  $a^0a^0c^-$  ( $I4/m$ ), and  $a^0b^-b^-$  ( $I2/m$ ) Glazer tilt systems are illustrated in Figure 7.4.

As shown in Figure 3, cell edges decrease with increasing  $\text{La}^{3+}$ , concurrent to

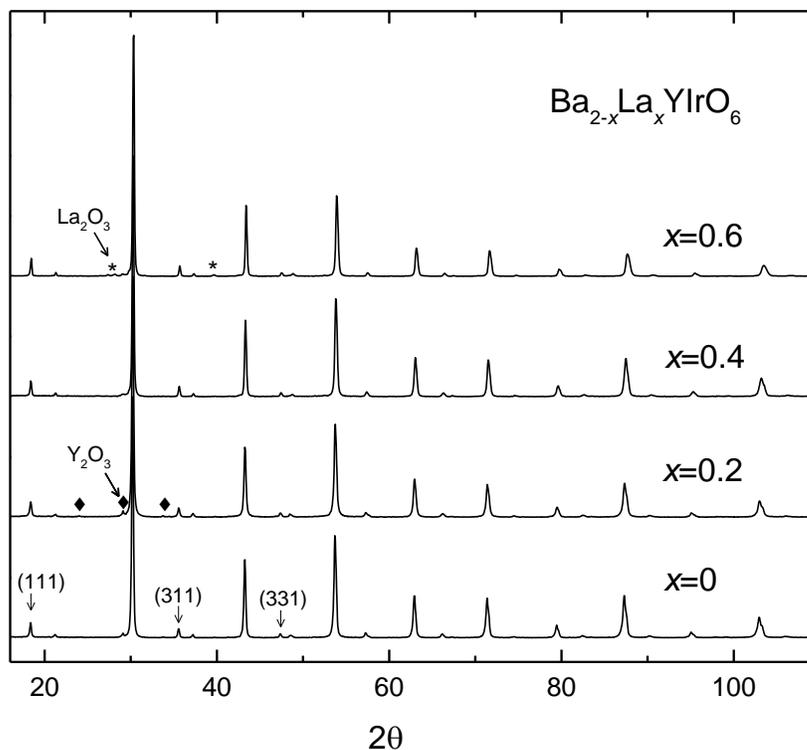

Figure 7.2: XRD patterns of  $\text{Ba}_{2-x}\text{La}_x\text{YIrO}_6$  ( $0 \leq x \leq 0.6$ ) samples shown from  $15\text{-}110^\circ$   $2\theta$ . A small presence of  $\text{La}_2\text{O}_3$  impurity exists for  $x \leq 0.6$  samples (asterisks). Trace  $\text{Y}_2\text{O}_3$  impurity phase was detected in the diffraction pattern upon magnification for all samples (diamonds).

the ionic radii difference between  $\text{Ba}^{2+}$  and  $\text{La}^{3+}$  ( $1.61 \text{ \AA}$  versus  $1.36 \text{ \AA}$ , respectively [200,201]. Deviation from the linear decrease of the  $a$  and  $b$  axis from  $x=0.4$  to  $x=0.6$  nominal samples can be attributed to the transformation to a Glaser 2-tilt distorted monoclinic structure. For  $\text{Ba}_2\text{YIrO}_6$ , both powder XRD and TOF neutron refinements reveal an ideal cubic perovskite with rock salt 1:1 B-site ordering ( $Fm\bar{3}m$ ), consistent with other work, tolerance factor ( $\tau=0.98$ ), and the

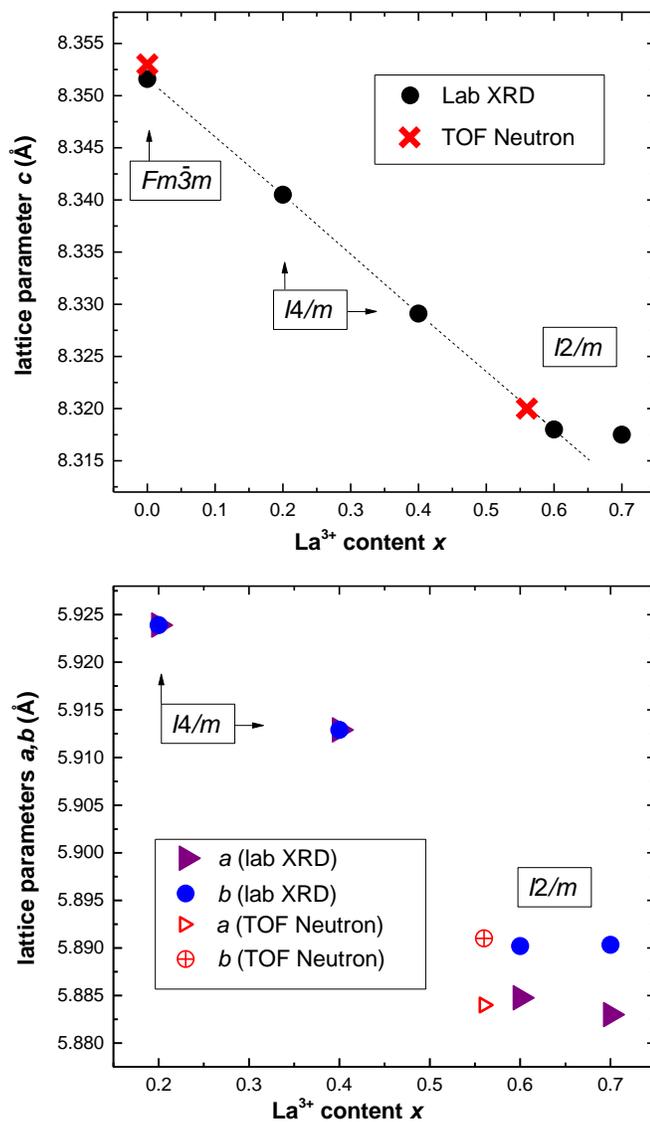

Figure 7.3: Cell edges  $a$ ,  $b$ , and  $c$  vs  $\text{La}^{3+}$  content  $x$  in  $\text{Ba}_{2-x}\text{La}_x\text{YIrO}_6$ . Lab XRD cell parameters are plotted by nominal  $\text{La}^{3+}$  content  $x$ . TOF neutron cell parameters are plotted by refined  $\text{La}^{3+}$  content  $x=0.56$ .

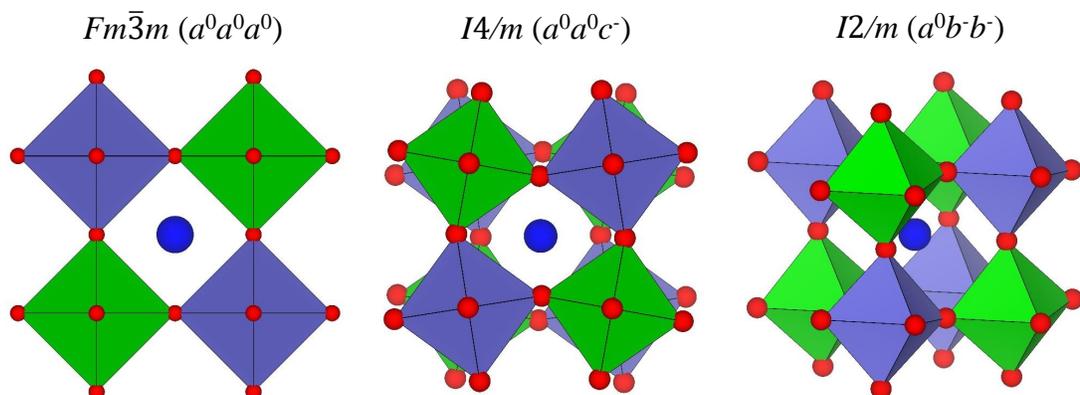

Figure 7.4: Illustration of  $A_2MM'O_6$  rock salt M-site ordered double perovskite structure looking down the  $c$ -axis of  $a^0a^0a^0$  ( $Fm\bar{3}m$ ),  $a^0a^0c^-$  ( $I4/m$ ), and  $a$ - $b$  plane of  $a^0b^-b^-$  ( $I2/m$ ) tilt systems. Here, A-site cations are represented as blue spheres and M/M' cations reside separately within the green and purple polyhedral sites.

common knowledge of M-site ordering influenced by corresponding size and charge difference [178–181, 184, 202, 203]. Metal 1:1 rock salt M-site ordering is shown by the presence of the (111), (311), and (331) peaks at  $18.5^\circ$ ,  $35.5^\circ$ , and  $47.5^\circ$   $2\theta$  respectively (Figure 7.2). With increasing  $La^{3+}$  content, XRD peak shapes and positions within  $70 - 110^\circ$   $2\theta$  prove difficult to refine with  $Fm\bar{3}m$  and suggest lower-symmetry structures. By substituting  $Ba^{2+}$  with the smaller radii of  $La^{3+}$  (1.61 Å versus 1.36 Å, respectively) [200, 201], octahedral tilting to accommodate the smaller A-site cation is conceivable, hence lower-symmetry structures will result. Several previous analyses report the space-group symmetries that result from the combination of octahedral tilting and octahedral-site cation ordering [204–206]. Neutron diffraction is ideal to establish this condition as oxygen has a coherent

neutron scattering length comparable to heavier atoms [207]. In addition, the neutron scattering lengths of Ba, La, Y, and Ir are each distinctive [207].

Additional reflections representing monoclinic doublets such as (110) and (002) are not present, eliminating 3-tilt distorted space-group symmetries [180,205,206]. Space-group symmetries associated to Glaser 1- and 2-tilt systems for 1:1 rock salt ordered double perovskites were therefore investigated [204–206]. For nominal composition  $\text{Ba}_{1.4}\text{La}_{0.6}\text{YIrO}_6$ , space-group symmetry was refined to be  $I2/m$ . Resulting TOF Neutron refinements are shown in Figure 7.5. Refined cell parameters and atomic information are presented in Tables 7.1 and 7.2.

The resulting refined compositions are  $\text{Ba}_2\text{Y}_{0.955(8)}\text{IrO}_{5.964(2)}$  and  $\text{Ba}_{1.442(4)}\text{La}_{0.558(4)}\text{Y}_{0.953(2)}\text{IrO}_{5.952(8)}$ . Occupancy refinements indicate that the iridium sites are fully occupied. For  $\text{Ba}_2\text{YIrO}_6$ , barium site occupancy was refined to be 1. The lanthanum content was refined to be slightly less than the expected  $x=0.6$ . This is consistent with the small presence of  $\text{La}_2\text{O}_3$  impurity. A small presence of yttrium and oxygen vacancies exist for both systems. Attempts of refining iridium in the yttrium site proved unsuccessful as iridium occupancy was refined to 0. Though 1:1 stoichiometric amounts of Y:Ir were used in the synthesis, the refined yttrium occupancy is considered reasonable as a small presence of  $\text{Y}_2\text{O}_3$  impurity is formed during the synthesis. Small presence of oxygen vacancies are common with perovskite systems. The A-site, Y, and Ir thermal parameters,  $U$ , are considered reasonable and consistent between both samples. A-site  $U$  are larger than Y/Ir  $U$ , consistent with similar systems [178–180,184]. A larger cation residing in a 12-coordinated environment is expected to possess a larger  $U$ . For  $Fm\bar{3}m$  sam-

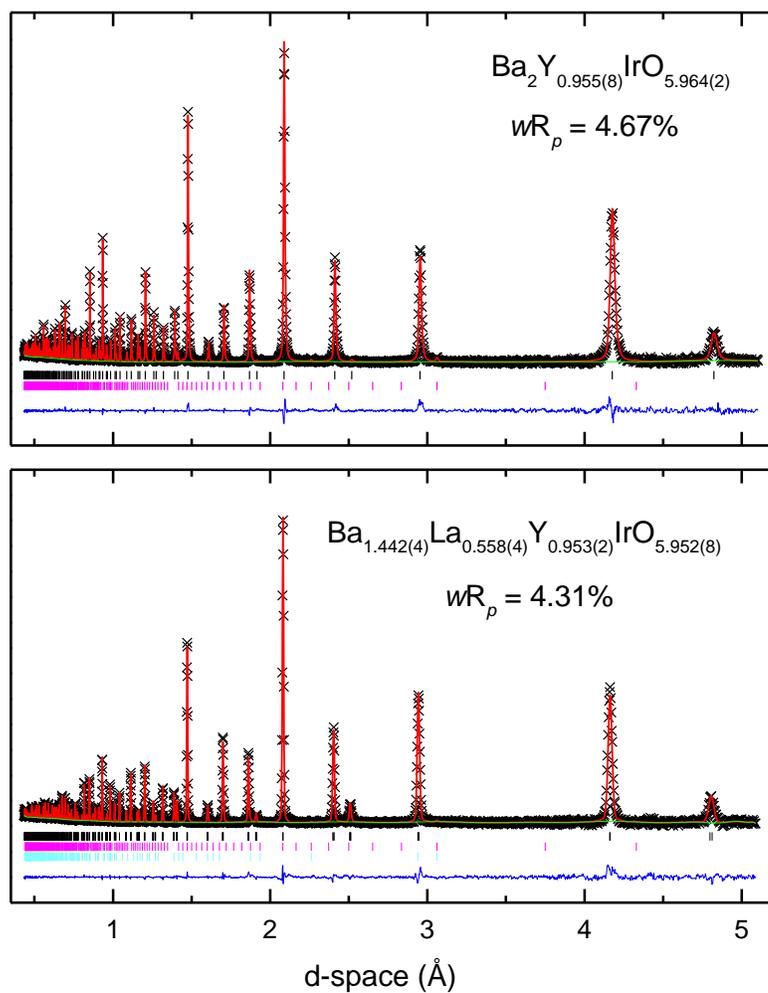

Figure 7.5: TOF Neutron refinement of nominal compositions  $\text{Ba}_2\text{YIrO}_6$  (top) and  $\text{Ba}_{1.4}\text{La}_{0.6}\text{YIrO}_6$  (bottom). Observed (black crosses) and calculated (solid red line) profiles, background (green), and difference curve ( $I_{obs} - I_{calc}$ ) (blue) are shown for each refinement. The vertical bars indicate the expected reflection positions with black, pink, and teal representing  $\text{Ba}_{2-x}\text{La}_x\text{YIrO}_6$ ,  $\text{Y}_2\text{O}_3$  ( $Ia\bar{3}$ ), and  $\text{La}_2\text{O}_3$  ( $P3\bar{m}1$ ) phases respectively. Resulting stoichiometric identities and  $wR_p$  are represented.

b) For  $Fm\bar{3}m$ , crystal structure refined in space group with A(Ba) at  $8c$  (1/4,1/4,1/4), Y at  $4a$  (0,0,0), Ir at  $4b$  (1/2,1/2,1/2), and O1 at  $24e$  ( $x,0,0$ ) sites, respectively.

c) For  $I2/m$ , crystal structure refined in space group with A(Ba/La) at  $4i$  ( $x,0,z$ ), Y at  $2a$  (0,0,0), Ir at  $2d$  (0,0,1/2), O1 at  $4i$  ( $x,0,z$ ), and O2 at  $8j$  ( $x,y,z$ ) sites, respectively.

ple, oxygen thermal parameters show disk-like ellipsoids, analogous to other corner shared octahedral systems. Oxygen  $U$  are slightly larger and more oval for  $I2/m$  sample, congruent with Glaser 2-tilt systems to accommodate the smaller A-site cation. For  $I2/m$  sample, the [001] octahedral tilt angles for yttrium and iridium are approximately  $4.3^\circ$ , consistent with other reported  $I2/m$  double perovskite systems [178–180, 184]. When comparing the average A-O bond distance, a slight reduction is observed with the incorporation of  $\text{La}^{3+}$  (Table 7.2). A portion of the  $\text{Ba}_2\text{Y}_{0.955(8)}\text{IrO}_{5.964(2)}$  ( $Fm\bar{3}m$ ) and  $\text{Ba}_{1.442(4)}\text{La}_{0.558(4)}\text{Y}_{0.953(2)}\text{IrO}_{5.952(8)}$  ( $I2/m$ ) unit cells from TOF neutron refinements are illustrated in Figure 7.6. Bond valence sums (BVS) were calculated and are reported in Table 7.2. Oxygen BVS are all close to 2. For the mixed A- ( $\text{Ba}^{2+}/\text{La}^{3+}$ ) and mixed iridium charge ( $\text{Ir}^{5+}/\text{Ir}^{4+}$ ) sites, BVS were calculated using the weighted average of the corresponding bond valance parameters. Such BVS values are analogous to what would be expected for iridium and A-site oxidation states based on refined composition. The yttrium cation, however, is observed to be over-bonded with BVS=3.39 for  $x=0$  and BVS=3.69 for  $x=0.56$  (Table 7.2). Attempts of fixing the yttrium occupancy to 1 makes an insignificant difference to the Y-O bond distances, and an overall increase in  $wR_p$  of the refinement is observed. Other known work on  $\text{Ba}_2\text{YIrO}_6$  also reveal yttrium being over-bonded with similar reported BVS [184]. For a cubic double perovskite system, if the tolerance factor ( $\tau$ ) is equal to 1.0, the A-O and B-O bonds can adopt their ideal lengths in the cubic structure [178, 208, 209]. When  $\tau < 1$ , the perovskite structure can compensate for the cation size mismatch by tilting the  $\text{MO}_6$  octahedra and/or by distorting the ideal bond lengths [178, 208, 210, 211].

Both tilting and bond length alteration can take place simultaneously to alleviate strain induced by cation size mismatch [178,208]. If  $\tau$  is only marginally less than 1 ( $\tau=0.98$  for  $\text{Ba}_2\text{YIrO}_6$ ), small structural strain tends to be relieved by a change of bond lengths, instead of octahedral tilting [178,208]. Comparable observations have been reported in other similar perovskite systems [184,208,210–215].

#### 7.4.2 Transport and Magnetic Properties

Temperature dependent resistivity and Seebeck measurements from 300–600 Kelvin for  $0 \leq x \leq 0.6$  samples are shown in Figure 7.7. Low temperature  $\rho(T)$  data from 75-300 Kelvin are shown in Figure 7.8. All samples are semiconducting. The reported electrical properties are consistent with previous reports [194].

With increasing  $\text{La}^{3+}$  content, the conductivity of the material increases and becomes  $n$ -type. The development of  $\text{Ir}^{4+/5+}$  sites with increasing  $\text{La}^{3+}$  content is projected to decrease the Hubbard  $U$  energy, thus empowering electron hopping. Low temperature transport measurements were analyzed using the general formula for variable range hopping (VRH)  $\rho=\rho_0\exp((T_0/T)^{1/(d+1)})$  where  $d$  is the dimensionality, and  $\rho_0$  and  $T_0$  are fitting parameters. The  $\chi^2$  of the fits for all compounds were minimized at  $d = 3$ . The differential activation energy was determined by differentiating  $\ln(\rho)$  with respect to  $(k_B T)^{-1}$  (Figure 7.8). An increase in the activation energy is observed with increasing temperature due to decreased hopping distance and increased energy difference between sites. With increasing  $\text{La}^{3+}$  content, the activation energy does decrease overall with the largest reduc-

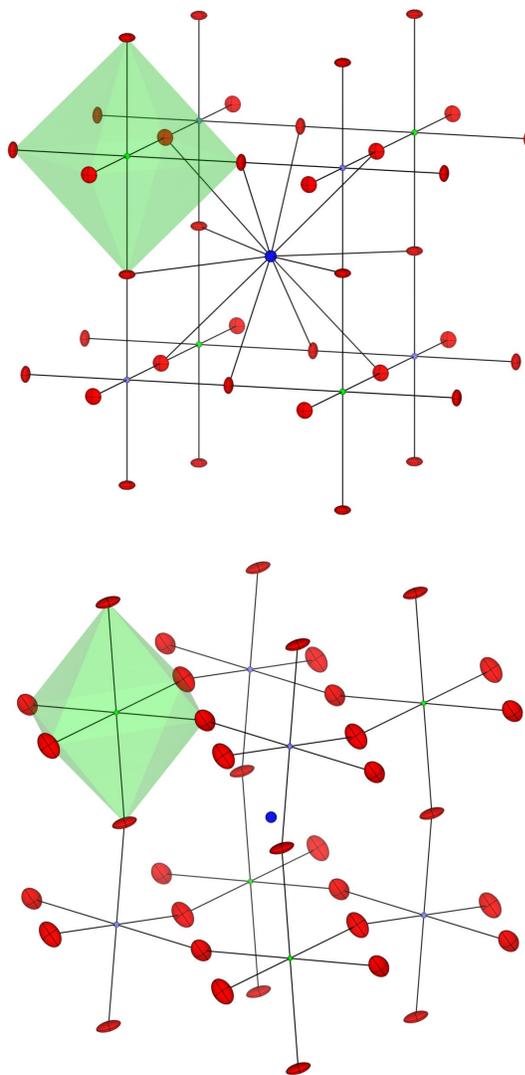

Figure 7.6: A portion of the  $\text{Ba}_2\text{Y}_{0.955(8)}\text{IrO}_{5.964(2)}$  ( $Fm\bar{3}m$ ) and  $\text{Ba}_{1.442(4)}\text{La}_{0.558(4)}\text{Y}_{0.953(2)}\text{IrO}_{5.952(8)}$  ( $I2/m$ ) unit cells from TOF neutron refinements with barium-lanthanum, yttrium, iridium, and oxygen thermal ellipsoids represented as blue, green, purple, and red respectively.

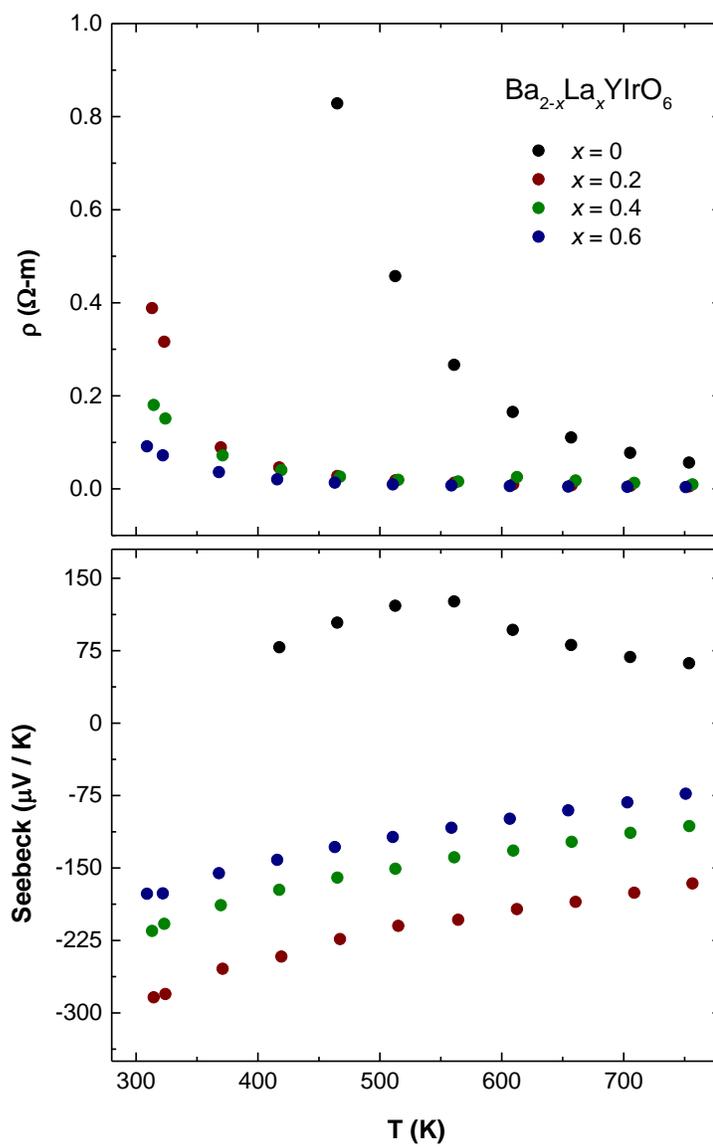

Figure 7.7: Temperature dependent resistivity (top) and Seebeck coefficient data (bottom) of  $\text{Ba}_{2-x}\text{La}_x\text{YrO}_6$  samples ( $0 \leq x \leq 0.6$ ) from 300 to 600 K.

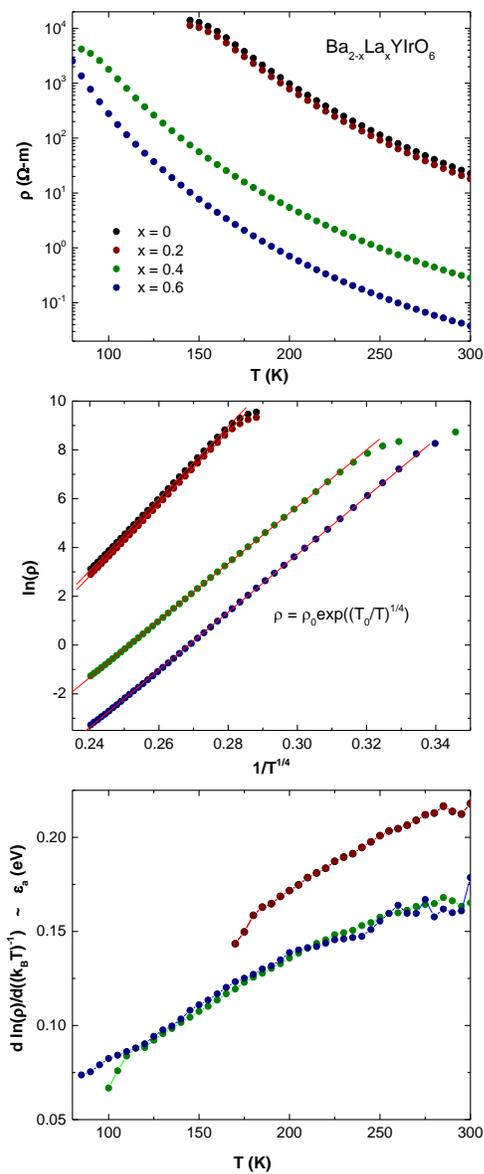

Figure 7.8: Temperature dependent, low temperature resistivity plots (top/middle) for  $\text{Ba}_{2-x}\text{La}_x\text{YrO}_6$  samples ( $0 \leq x \leq 0.6$ ) and the differential activation energy determined by differentiating  $\ln(\rho)$  with respect to  $(k_B T)^{-1}$  (bottom) from 75 to 300 K.

tion going from  $x=0.2$  to  $x=0.4$ . The magnetic susceptibility  $\chi$  ( $H = 0.5$  T) was measured for  $0 \leq x \leq 0.8$  samples and shows the combined effects of a Curie-Weiss effective moment ( $\mu_{eff}$ ) presumably originating from  $\text{Ir}^{4+}$  and a van Vleck temperature independent paramagnetism ( $\chi_{VV}$ ), which is known for  $\text{Ir}^{5+}$ . In Figure 7.9 are shown the data with  $\chi_{VV}$  subtracted, and then multiplied by  $T$ , along with fits to a Curie-Weiss form. For  $x=0$  and 0.6 nominal samples, a small bump exists in the magnetic susceptibility at 55 K. A small presence of a second phase, undetectable with XRD, is likely the cause. The 5M  $\text{BaIrO}_3$  phase is known to have a ferromagnetic transition at  $\sim 55$  K [216].

The value of  $\chi_{VV}$  used for each  $x$  is that which, after subtraction from  $\chi(T)$ , produces the best fit to a Curie-Weiss form, yielding  $\mu_{eff}$  values of 0.304, 0.577, 0.883, 1.001, and 1.071  $\mu_B$  for  $x = 0, 0.2, 0.4, 0.6,$  and  $0.8$  respectively. We test the assumption that  $x$  tunes between 100%  $d^4$  for  $x = 0$  to 80%  $d^5$  for  $x = 0.8$  in Figure 7.10. Here we plot the fraction of  $\text{Ir}^{4+}$  moments that would give rise to the  $\mu_{eff}$  values, assuming a moment of 1.73  $\mu_B$  for each  $\text{Ir}^{4+}$ . Also plotted is the obtained  $\chi_{VV}(x)$  divided by the  $x = 0$  value which, for a simple mixed valence situation, would range from 1.0 for  $x = 0$  to 0.2 for  $x = 0.8$ . Clearly, we see deviations from this mixed valence picture, not only for  $x = 0.2$ , but also on approaching  $x = 0.8$ . The  $x = 0$  sum is 1 by construction. For  $x = 0.2$ ,  $\chi_{VV}$  is larger than found for  $x = 0$ . For  $x = 0$ ,  $\chi_{VV}$  is expected to be the largest as this compound is nominally all  $\text{Ir}^{5+}$ . The presence of oxygen vacancies might account for the deviations in the mixed valence picture. Because the neutron scattering length for oxygen is comparable to most metals [207], oxygen occupancy refinement is

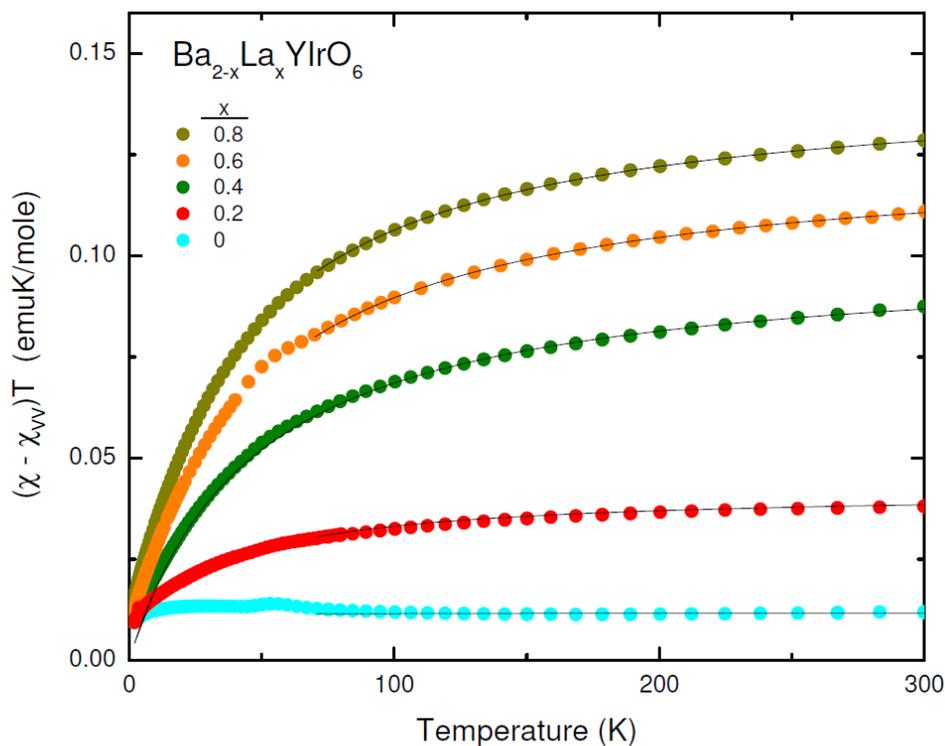

Figure 7.9: Magnetic susceptibility  $\chi$  ( $H = 0.5$  T) measured for  $0 \leq x \leq 0.8$  samples are shown with  $\chi_{VV}$  subtracted, and then multiplied by T, along with fits to a Curie-Weiss form.

accurate with neutron refinements. Our reported neutron refinements reveal an oxygen occupancy of 0.994(4) and 0.988(2) for  $x=0$  and  $x=0.6$  nominal samples, respectively (Table 7.1). Such a small presence of vacancies clearly cannot explain such deviations in the mixed valence picture. Because all samples were synthesized under the same condition, it is unlikely  $x=0.2$  and  $0.4$  nominal samples possess

a greater presence of oxygen vacancies and therefore likely does not elucidate the mixed valence picture. Work by Kataev et al reveal a few percent of  $\text{Ir}^{6+}$  magnetic defects in  $\text{Ba}_2\text{YIrO}_6$ , determined by ESR spectroscopy [186]. Deviation from the expected simple  $\text{Ir}^{4+/5+}$  mixed valence state might exist for  $x > 0$  samples due to the presence of  $\text{Ir}^{6+}$  magnetic defects. Thus, studies with ESR spectroscopy might be able to clarify the observed mixed valence picture.

## 7.5 Summary

The motivation to study  $\text{Ba}_{2-x}\text{La}_x\text{YIrO}_6$  was to elucidate the influence of noncubic symmetry on the electronic and magnetic properties of such iridate perovskites. With increasing  $\text{La}^{3+}$  content, the conductivity of the material increases and becomes  $n$ -type. The development of  $\text{Ir}^{4+/5+}$  sites with increasing  $\text{La}^{3+}$  content is projected to decrease the Hubbard  $U$  energy, thus empowering electron hopping. As shown by the structural refinements presented,  $a^0a^0a^0 (Fm\bar{3}m) \rightarrow a^0b^-b^- (I2/m)$  octahedral distortion of the  $\text{YO}_6\text{-IrO}_6$  rock-salt framework occurs with increasing  $x$  to account for the incorporation of smaller  $\text{La}^{3+}$  radii. From the magnetic susceptibility measurements, deviations from the proposed mixed valence picture are observed, not only for  $x = 0.2$ , but also on approaching  $x = 0.8$ . For  $x = 0.2$ ,  $\chi_{VV}$  is larger than found for  $x = 0$ .

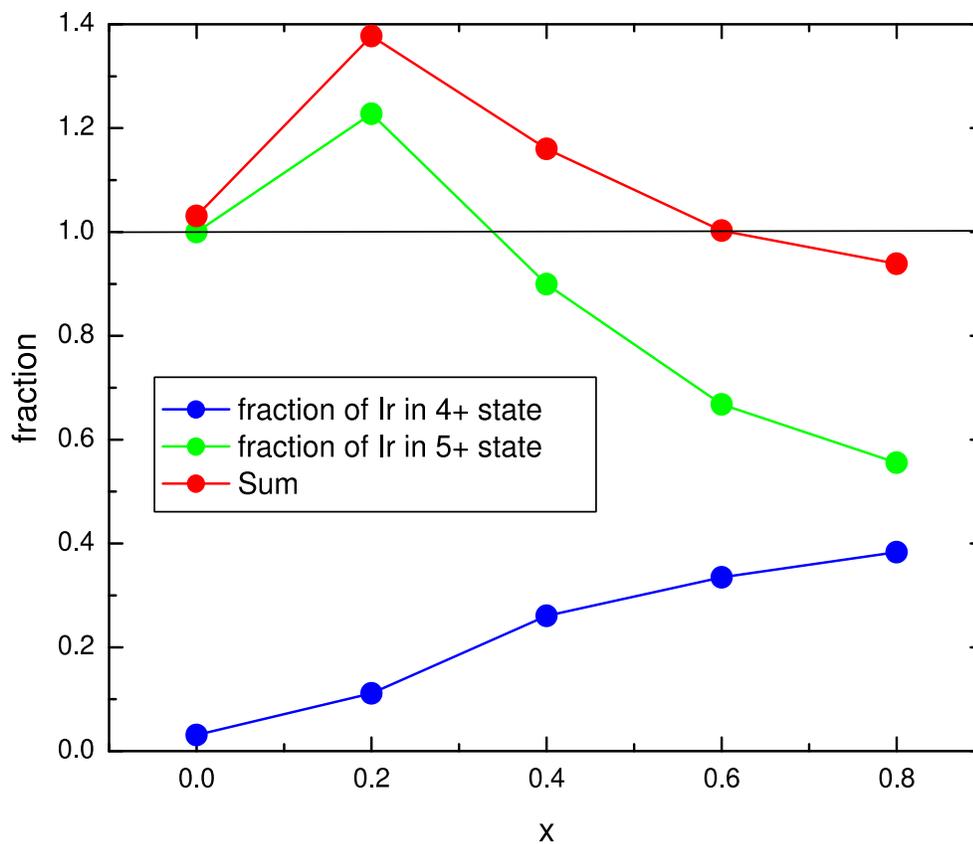

Figure 7.10: Blue symbols – Variation of the inferred density of  $s = \frac{1}{2}$  spins expressed as a fraction of the total Ir concentration versus  $x$  in  $\text{Ba}_{2-x}\text{La}_x\text{YIrO}_6$ . Green symbols – Variation of Van Vleck temperature independent susceptibility expressed as a fraction of the value obtained at  $x = 0$  versus  $x$ . ## Chapter 8: Structural and Electronic Properties of $\text{Cu}[\text{Ir}_{1.5}\text{Cu}_{0.5}]\text{O}_4$ Spinel

### 8.1 Abstract

Frustrated systems populated with large spin-orbit coupled (SOC) ions are an ideal setting for the exploration of exotic states. Among the known frustrated frameworks, the spinel structure has been extensively investigated. Though many spinel systems with  $3d/4d$  elements exist, to our knowledge, an Iridium based spinel oxide has not been reported. Most spinel oxides are known to be insulating and only two,  $\text{LiV}_2\text{O}_4$  and  $\text{LiTi}_2\text{O}_4$ , are reported as conducting. A frustrated mixed valence system that is metallic and exhibits large SOC is scarce, and if a metallic spinel is close to a correlation driven metal-insulator transition, a novel interplay between the charge carriers and the frustrated spin degree of freedom is anticipated. Here we present the first Iridate spinel:  $\text{Cu}[\text{Ir}_{1.498(1)}\text{Cu}_{0.502(1)}]\text{O}_4$ . Synchrotron XRD refinements reveal a face-centered cubic structure with space group  $Fd\bar{3}m$ . Electrical properties reveal a metallic state within 50~600 K range with a Kondo-effect at  $T < 50$  K.

## 8.2 Introduction

Frustrated systems populated with large spin-orbit coupled (SOC) ions are an ideal setting for the exploration of exotic states. Among the known frustrated frameworks, the spinel structure has been extensively investigated. The general formula for a spinel is  $[A_{1-\gamma}M_\gamma]^{tet}[M_{2-\gamma}A_\gamma]^{oct}O_4$ , where  $\gamma$  represents the fraction of M and A cations on the tetrahedral and octahedral sites, respectively. The  $M_2O_4$  octahedral network forms a rock salt structure with alternate octahedral sites occupied by the M-cations. The A-cation occupies 1/8 of the tetrahedral sites with all four neighboring octahedral sites empty. One of the unique features of the spinel structure is that the M-cations form a sub-lattice of corner-shared tetrahedra and the A-cations form a diamond sublattice (Figure 8.1).

If the sublattice framework is populated with magnetic ions, strong magnetic frustration can occur. Though many spinel systems exist with  $3d/4d$  elements, to our knowledge, an Iridium based spinel oxide has not been reported. The SOC for iridium is 540 meV [217]. A spinel framework populated by M-ions with SOC comparable to iridium is not known. The SOC of iridium is large enough to influence the electronic states. Iridates are the most widely studied with Iridium frequently in a 4+ oxidation ( $5d^5$ ) state [218–220], resulting in a  $s = \frac{1}{2}$  Kramers doublet. Various systems with such  $5d^5$  ground states have been predicted to possess anisotropic exchange interactions, a key ingredient of the Kitaev model of quantum spin liquid [221]. Most spinel oxides are known to be insulating and only two spinel oxides,  $LiV_2O_4$  and  $LiTi_2O_4$ , are reported as conducting [222]. A frus-

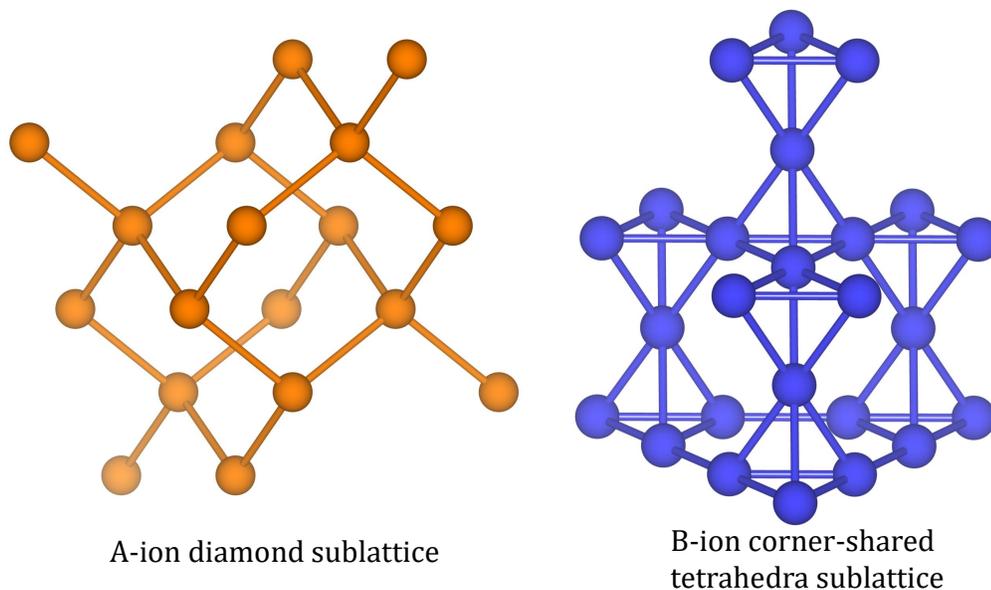

Figure 8.1: The A-ions form a diamond sublattice and the B-ions form a sublattice of corner-shared tetrahedra within the spinel structure.

trated mixed valence system that is metallic and exhibits large SOC is scarce, and if a metallic spinel is close to a correlation driven metal-insulator transition, a novel interplay between the charge carriers and the frustrated spin degree of freedom is anticipated. Here we present the first Iridate spinel:  $\text{Cu}[\text{Ir}_{1.498(1)}\text{Cu}_{0.502(1)}]\text{O}_4$ . Synchrotron XRD refinements reveal a face-centered cubic structure with space group  $Fd\bar{3}m$ . Electrical properties reveal a metallic state within 50~600 K range with a Kondo-effect at  $T < 50$  K.

### 8.3 Experimental

Polycrystalline  $\text{Cu}[\text{Ir}_{1.498(1)}\text{Cu}_{0.502(1)}]\text{O}_4$  was prepared via the synthesis of the hyperkagome structure  $\text{Na}_4\text{Ir}_3\text{O}_8$  and then an ion-flux exchange approach using  $\text{CuCl}$ . The compounds  $\text{Na}_2\text{CO}_3$  and  $\text{IrO}_2$  with the correct stoichiometric ratio ( $\text{Na}_4\text{Ir}_3\text{O}_8$ ) were ground and pressed into 10 mm diameter pellets. The resulting pellet was fired at 750 C for 16 hrs, ground, and then reheated to 1000 C for 18 hrs before being quenched using a water bath. The resulting hyperkagome  $\text{Na}_4\text{Ir}_3\text{O}_8$  sample was mixed with molar excess of  $\text{CuCl}$  and then fired at 450 C under an argon flow. The sample was then washed with a dilute nitric acid solution to remove remaining  $\text{NaCl}$  and excess  $\text{CuCl}$  and  $\text{Cu}$  metal. Phase analysis of powder samples was performed by X-ray diffraction using a Rigaku MiniFlex II diffractometer with  $\text{Cu K}_\alpha$  radiation and a graphite monochromator for the diffracted beam. Synchrotron X-ray Diffraction (Advanced Photon Source 11-BM) was collected at room temperature ( $\lambda=0.412833$  Å,  $2\theta < 50$ ). The principal thermoelectric properties; the Seebeck coefficient ( $S$ ), electrical conductivity ( $\sigma$ ), and thermal conductivity ( $k$ ) were measured from 300~600K. The Seebeck coefficient and electrical conductivity data was collected on an ULVAC ZEM-3 under a helium atmosphere. Low-temperature (5-300 K) magnetization measurements were obtained with a Quantum Design MPMS and resistivity (50-300 K) measurements were obtained using a Quantum Design PPMS.

## 8.4 Results

Powder X-ray diffraction pattern of  $\text{Cu}[\text{Ir}_{1.498(1)}\text{Cu}_{0.502(1)}]\text{O}_4$  reveals face-centered cubic structure with space group  $Fd\bar{3}m$  (Figure 8.2). Trace  $\text{IrO}_2$  impurity phase was detected in the diffraction pattern upon magnification (Figure 8.2, asterisk symbol).

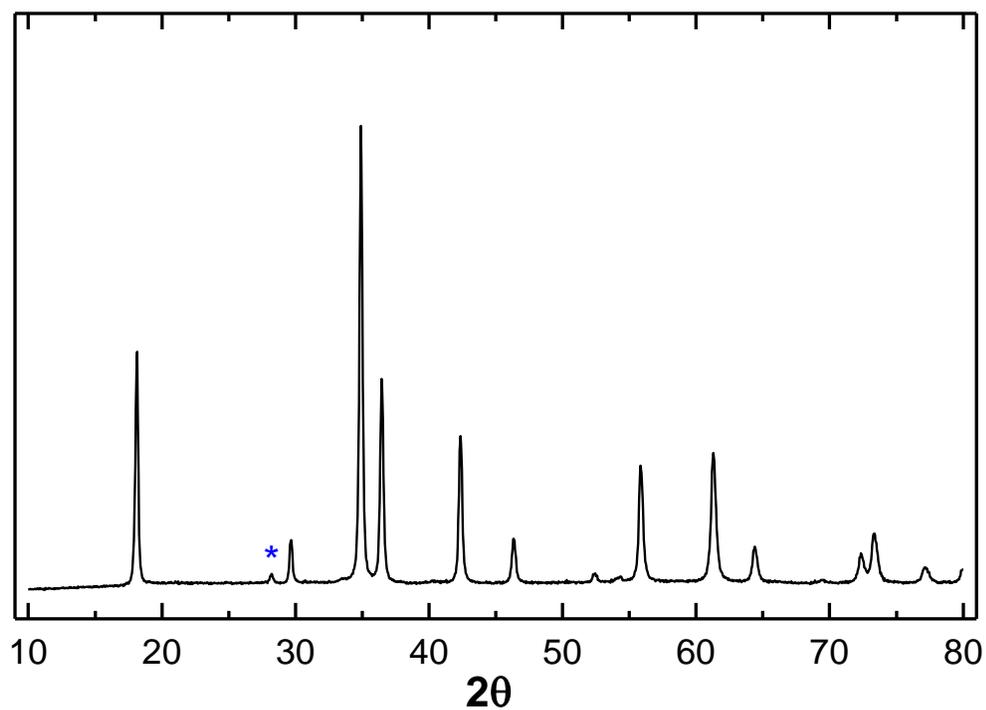

Figure 8.2: Powder XRD pattern of  $\text{Cu}[\text{Ir}_{1.5}\text{Cu}_{0.5}]\text{O}_4$  sample. Blue asterisk symbol indicates a small presence of  $\text{IrO}_2$  impurity phase.

To determine the crystal structure, Rietveld refinements were performed on

synchrotron XRD data collected at APS 11bm beamline ( $\lambda=0.412833$  Å) using the GSAS program. Room temperature synchrotron XRD was collected up to  $2\theta$ . A pseudo-Voigt peak shape profile was chosen, and parameters refined to obtain the best fit to the collected data. The space group was refined to be  $Fd\bar{3}m$ . Trace  $\text{IrO}_2$  impurity phase was detected in the diffraction pattern upon magnification. Resulting synchrotron XRD Rietveld refinement for  $\text{Cu}[\text{Ir}_{1.498(1)}\text{Cu}_{0.502(1)}]\text{O}_4$  is shown in Figure 8.3.

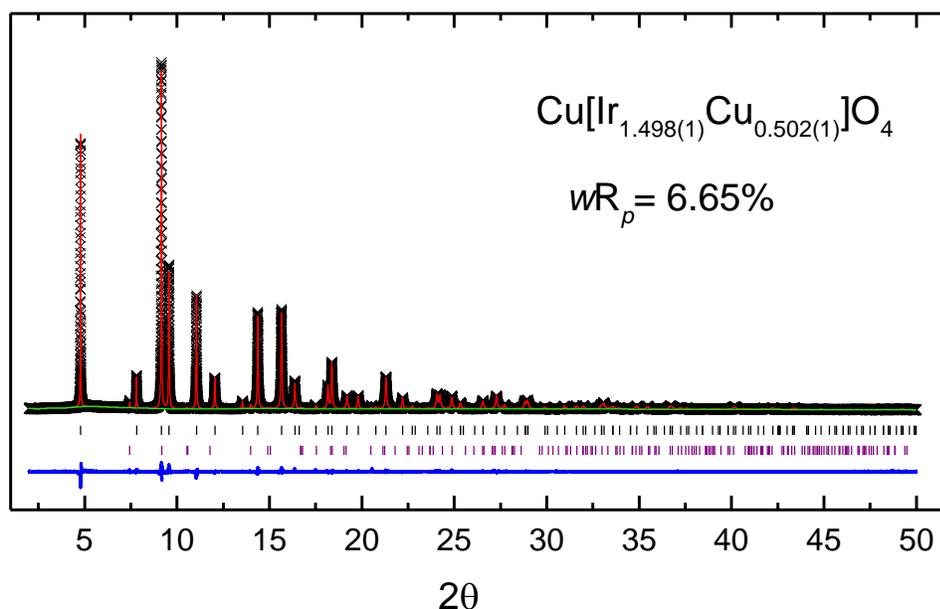

Figure 8.3: Synchrotron Rietveld refinement of  $\text{Cu}[\text{Ir}_{1.5}\text{Cu}_{0.5}]\text{O}_4$  sample at room temperature ( $\lambda=0.412833$  Å). Observed (black crosses) and calculated (solid red line) profiles, background (green), and difference curve ( $I_{obs} - I_{calc}$ ) (blue) are shown. The vertical bars indicate the expected reflection positions for spinel ( $Fd\bar{3}m$ ) phase (black) and  $\text{IrO}_2$  impurity phase (purple). Resulting stoichiometric identity and  $wR_p$  are represented.

The detailed results are given in Table 8.1. Refined lattice parameters are in

accordance of  $\text{CuRh}_2\text{O}_4$  normal spinel ( $Fd\bar{3}m$ ) [223].

From the refined parameters provided in Table 8.1, the tetrahedral  $8a$  site was refined to be occupied by copper with an occupancy of 1. Iridium is too large for a tetrahedral site and any addition of Iridium in the  $8a$  site proved not stable in the refinement. Refinement of sodium in the tetrahedral  $8a$  site or neighboring empty  $16c$  octahedral sites also were not stable with the occupancy refining to zero. Incorporation of copper on the octahedral  $16d$  site did result in an overall more stable refinement. The resulting  $16d$  refined occupancies reveal 75% of the respective site occupied by iridium with the remaining 25% occupied by copper. The  $\text{A}_4\text{M}_3\text{O}_8$  hyper-kagome edge shared octahedral framework is analogous to the spinel framework, except 1/4 of the edge shared octahedral sites are occupied by the A-cation (compared to all 1/2 of the octahedral sites occupied by M in the normal  $\text{AM}_2\text{O}_4$  spinel structure). In addition, molar excess  $\text{CuCl}$  was used in the ion-exchange process. Thus, Na-Cu exchange resulting in 25% of the  $16d$  site occupied by copper is considered logical. Refinements were performed with  $\text{Na}^+$  occupying the  $16d$  site, however, such refinements were proven to not be stable. If we assume Cu residing on the tetrahedral  $8a$  site has an oxidation state of 1+ ( $d^{10}$ ) and Cu occupying the octahedral  $16d$  site has an oxidation state of 2+ ( $d^9$ ), the overall charge of the refined stoichiometric identity (assuming  $\text{Ir}^{4+}$ ) equates to zero. Any alternate combinations of  $\text{Cu}^{1+/2+}$  in the tetrahedral/octahedral sites results in the overall charge of the refined stoichiometric identity not equating to zero (assuming  $\text{Ir}^{4+}$ ). In addition, calculated BVS match best with the expected oxidation states if  $\text{Cu}^+$  is assumed for the tetrahedral  $8a$  site and  $\text{Cu}^{2+}$  for the

a) Synchrotron XRD diffraction data collected at APS 11-BM (room temperature).

b) For  $Fd\bar{3}m$ ,  $\text{AM}_2\text{O}_4$  crystal structure refined in space group with A(Cu) at 8a (1/8,1/8,1/8), M(Cu/Ir) at 16d (1/2,1/2,1/2), and O at 32e ( $x,x,x$ ) sites.

octahedral  $16d$  site (Table 8.1 and Table 8.2).

Based on the crystal field stabilization energy (CFSE),  $\text{Cu}^+$  ( $d^{10}$ ) has no preference for tetrahedral or octahedral sites and because of the relatively small ionic size, tetrahedral site would be preferred. From CFSE, the Jahn-teller active  $\text{Cu}^{2+}$  ( $d^9$ ) would prefer an octahedral site and would also suggest a non-cubic system. Lower symmetry space groups, such as  $I41/amd$  were investigated to account for the possible Jahn-teller distortion of  $\text{Cu}^{2+}$  on the octahedral  $16d$  site. Such lower symmetry space groups require additional hkl peaks which were not present in the synchrotron XRD data, suggesting the higher symmetry  $Fd\bar{3}m$  which account for all peaks. Because 75% of the octahedral  $16d$  site is occupied by  $\text{Ir}^{4+}$ , which is not considered Jahn-teller active, cubic  $Fd\bar{3}m$  is considered reasonable.

Temperature dependent resistivity and Seebeck measurements from 300–600 Kelvin for the  $\text{Cu}[\text{Ir}_{1.498(1)}\text{Cu}_{0.502(1)}]\text{O}_4$  sample are shown in Figure 8.4. Low temperature  $\rho(T)$  data from 5-300 Kelvin are shown in Figure 8.5. Electrical properties reveal a metallic state within 50~600 K range with a Kondo-effect at  $T < 50$  K.

## 8.5 Summary

If a metallic spinel is close to a correlation driven metal-insulator transition, a novel interplay between the charge carriers and the frustrated spin degree of freedom is anticipated. Synchrotron XRD refinements reveal a face-centered cubic structure with space group  $Fd\bar{3}m$ . Electrical properties reveal a metallic state within 50~600 K range with a Kondo-effect at  $T < 50$  K.

Table 8.2: A list of calculated bond valence sums (BVS) for each element in  $\text{Cu}[\text{Ir}_{1.498(1)}\text{Cu}_{0.502(1)}]\text{O}_4$  based on the assigned oxidation state of copper. The overall charge of the refined stoichiometric identity is calculated based on the assigned oxidation states of Cu and Ir. The Resulting BVS are compared to the expected oxidation state (Exp. ox.) and the difference between BVS and Exp. ox. is calculated ( $\Delta$ )

## Chapter 9: Structural, Electronic, and Thermal Properties of Indium-Filled $\text{In}_x\text{Ir}_4\text{Sb}_{12}$ Skutterudites

### 9.1 Abstract

The “phonon-glass/electron-crystal” approach has been implemented through incorporation of “rattlers” into skutterudite void sites to increase phonon scattering and thus increase the thermoelectric efficiency. Indium filled  $\text{IrSb}_3$  skutterudites are reported for the first time. Polycrystalline samples of  $\text{In}_x\text{Ir}_4\text{Sb}_{12}$  ( $0 \leq x \leq 0.2$ ) were prepared by solid-state reaction under a gas mixture of 5%  $\text{H}_2$  and 95% Ar. The solubility limit of  $\text{In}_x\text{Ir}_4\text{Sb}_{12}$  was found to be close to 0.18. Synchrotron X-ray diffraction refinements reveal all  $\text{In}_x\text{Ir}_4\text{Sb}_{12}$  phases crystallized in body-centered cubic structure (space group:  $Im\bar{3}$ ) with 8% antimony site vacancy and with indium partially occupying the  $16f$  site. Unlike known rattler filled skutterudites, under synthetic conditions employed, indium filling in  $\text{IrSb}_3$  significantly increases the electrical resistivity and decreases the Seebeck coefficient ( $n$ -type) while reducing the thermal conductivity by 30%. The resultant power factor offsets the decrease in total thermal conductivity giving rise to a substantial decrease in  $ZT$ . Principal thermoelectric properties of  $\text{In}_x\text{M}_4\text{Sb}_{12}$  ( $\text{M} = \text{Co}, \text{Rh}, \text{Ir}$ ) phases are compared. As iridium is a  $5d$  transition metal, zero field cooled (ZFC) magnetization were performed to unravel the effect of spin-orbit interaction on the electronic properties.

These results serve to advance the understanding of filled skutterudites, and provide additional insight on the less explored smaller “rattlers” and their influence on key thermoelectric properties.

Publication based on this chapter:

1. M.K. Wallace, J. Li, and M.A. Subramanian, Structural, electronic, and thermal properties of indium-filled  $\text{In}_x\text{Ir}_4\text{Sb}_{12}$  skutterudites, *Solid State Sciences*, 80:170-177, 2018.

## 9.2 Introduction

Because of the unique structure and recognized ability to tune key transport properties, skutterudites are known to be strong thermoelectric candidates. The skutterudites are one well known class of Zintl compounds. As shown in Figure 9.1, the skutterudite crystal structure can be described in two ways: (a) a repeated corner-sharing  $\text{MX}_6$  arrangement with two  $\text{M}_4\text{X}_{12}$  formula units and two large empty cages per unit cell, or (b) an open cage like structure of cube-connecting M atoms with three fourths of the void sites filled with  $\text{X}_4$  Zintl polyanions, where M is a transition metal atom (M = Fe, Co, Rh, or Ir) and X is a pnictogen atom (X = P, As or Sb). The general formula is  $\text{MX}_3$  with cubic space group  $Im\bar{3}$ . The M cations occupy the  $8c$  (1/4, 1/4, 1/4) site and the X anions occupy the  $24g$  (0,  $y$ ,  $z$ ) site with  $y \sim 0.15$  and  $z \sim 0.34$ .

The thermoelectric performance of a material is characterized by the thermoelectric figure of merit,  $ZT = \frac{\sigma S^2 T}{K}$ , where  $S$  is the Seebeck coefficient,  $\sigma$  is the electrical conductivity,  $T$  is the effective temperature, and  $K$  is the summation of the lattice and electronic components of the total thermal conductivity ( $K_L + K_e$ ) (Chapter 3.3) [224–226]. An increase in thermoelectric performance corresponds to an increase in the  $ZT$  value. There are several approaches to optimize  $ZT$  such as nanostructuring techniques, alloying, and transition metal/pnictogen-site doping (Chapter 3.4) [225–229]. Another method to maximize  $ZT$  is by filling the unoccupied empty cages within M cube framework (Figure 9.1) with an ion. The empty cages can be filled by an ion A, leading to the formula  $\text{A}_y\text{M}_4\text{X}_{12}$  with  $y \leq$

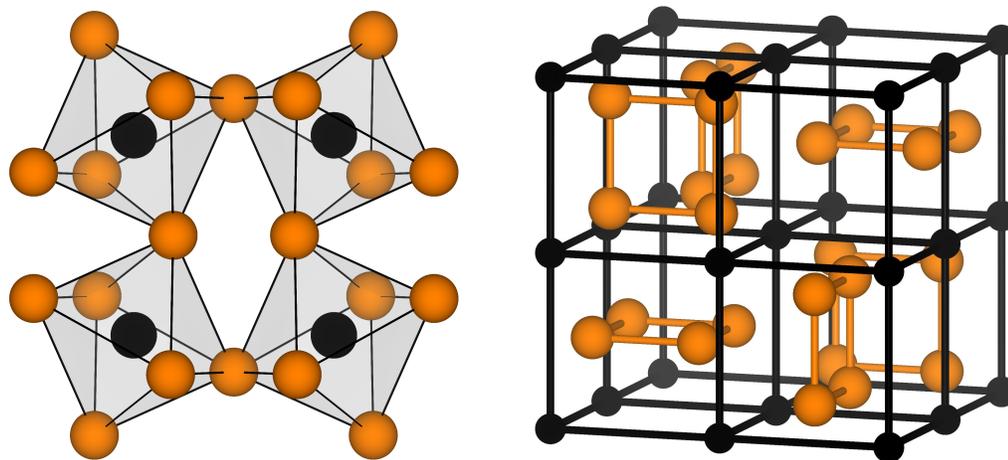

Figure 9.1: Skutterudite crystal structure shown as (a) a repeated corner-sharing  $\text{MX}_6$  arrangement and (b) cube-forming M atoms with three fourths of the void sites filled with  $\text{X}_4$  Zintl polyanions.

1. Because of the large size difference between the corresponding filler atom and void site, the filler atom can conceivably act as an independent oscillator and thus dampen the thermal phonon conductivity and decrease the total thermal conductivity (Chapter 3.4.1) [230–232]. Filling skutterudite voids can also influence the electrical conductivity, albeit the effect is usually negligible with respect to the decrease in total thermal conductivity [225, 230–232]. Though there is much work regarding the use of rare earth, alkali earth, or IVA group elements to fill the voids of various skutterudite structures, little work on indium filled skutterudites have been achieved [224–233]. The  $\text{IrSb}_3$ -based skutterudite compounds have shown potential for thermoelectric applications due to high Hall mobility [234–236]. Though many rare earth and alkali earth filled  $\text{IrSb}_3$  have been reported, to our knowledge,

investigation of indium filled  $\text{In}_x\text{Ir}_4\text{Sb}_{12}$  has not been addressed. It is suggested a smaller filler atom can possess greater rattler displacement, and thus enhance dampening of the lattice thermal conductivity [237, 238]. This corresponding enhancement is observed for indium filled  $\text{In}_x\text{Co}_4\text{Sb}_{12}$  showing an overall increase in ZT [232]. Yet for  $\text{In}_x\text{Ir}_4\text{Sb}_{12}$ , with increasing indium content, the observed increase in electrical resistivity outweighs the decrease in total thermal conductivity, revealing a significant reduction in ZT. With the prospect of new science and technology of topological insulators (TI), systems with strong spin-orbit coupling (SOC) are of great interest within the solid state science community [239]. Strong SOC systems have shown to exhibit many unconventional properties that challenge existing theory. Heavy metal alloys are of interest to better understand TI behavior. Iridium has one of the strongest SOC among magnetic *d*-electron elements [240]. In addition, certain indium based metal alloys reveal promising SOC behavior, supporting TI behavior [241–243]. There has been much theoretical work on potential TI heavy metal based skutterudite candidates [244–246]. Yet, key physical properties that address the prospect of topologically insulating behavior for metal alloy systems are lacking. Principal thermoelectric properties, zero field cooled (ZFC) magnetization, and structure properties are presented for indium filled  $\text{In}_x\text{Ir}_4\text{Sb}_{12}$ .

## 9.3 Results and Discussion

### 9.3.1 Structural Properties

Powder X-ray diffraction patterns reveal all  $\text{In}_x\text{Ir}_4\text{Sb}_{12}$  ( $x \leq 0.2$ ) in a body-centered cubic structure with space group  $Im\bar{3}$  (Figure 9.2). For  $\text{In}_x\text{Ir}_4\text{Sb}_{12}$  samples where  $x > 0.1$ , trace  $\text{InSb}$ ,  $\text{IrSb}_2$  and  $\text{Sb}$  impurity phases were detected in the diffraction pattern upon magnification (Figure 9.2, asterisk symbol). As shown in Figure 9.3, lattice variation with indium filling fraction indicates a minor increase in the cell edge and an indium solubility limit of approximately  $x = 0.18$ , which was also observed for  $\text{In}_x\text{Rh}_4\text{Sb}_{12}$  and  $\text{In}_x\text{Co}_4\text{Sb}_{12}$  [232, 237]. The obtained lattice parameters are in accordance with previous work on  $\text{IrSb}_3$ ,  $\text{In}_x\text{Rh}_4\text{Sb}_{12}$  and  $\text{In}_x\text{Co}_4\text{Sb}_{12}$  [232, 234, 235, 237].

To determine the crystal structure, Rietveld refinements were performed on synchrotron XRD data collected at APS 11bm beamline ( $\lambda = 0.412731 \text{ \AA}$ ) using the GSAS program. Room temperature synchrotron XRD was collected up to  $50^\circ 2\theta$  for  $x = 0, 0.1$ , and  $0.15$  and  $70^\circ 2\theta$  for  $x = 0.1$  nominal samples. Synchrotron XRD scans for  $x = 0$  and  $0.1$  nominal samples show no presence of impurities (small existence of  $\text{IrSb}_2$  and  $\text{Sb}$  phases in  $x = 0.15$ ). A pseudo-Voigt peak shape profile was chosen and parameters refined to obtain the best fit to the collected data. For all systems, the space group was refined to be  $Im\bar{3}$ . Resulting synchrotron XRD Rietveld refinements for nominal compositions  $\text{IrSb}_3$  and  $\text{In}_{0.1}\text{Ir}_4\text{Sb}_{12}$  collected at room temperature and 100 K are shown in Figure 9.4. The detailed results are given in Table 9.1.

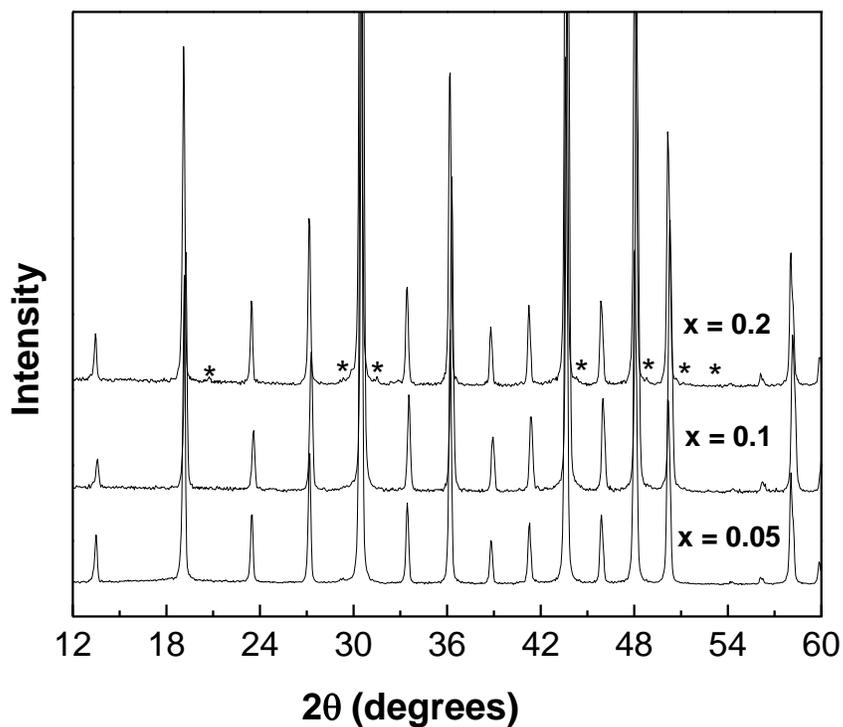

Figure 9.2: XRD patterns of  $\text{In}_x\text{Ir}_4\text{Sb}_{12}$  ( $x = 0.05, 0.1$  and  $0.2$ ) samples. Asterisk symbols indicate small presence of  $\text{IrSb}_2$ ,  $\text{InSb}$ , and  $\text{Sb}$  impurity phases.

To successfully refine the indium in the structure, room temperature and low temperature ( $T = 100$  K) synchrotron XRD data were collected up to  $70^\circ 2\theta$  for nominal  $\text{In}_{0.1}\text{Ir}_4\text{Sb}_{12}$  sample, and the refined crystal structure is shown in Figure 9.5. At both room temperature and 100 K, indium was refined to partially occupy the  $16f$  position with stoichiometric identity  $\text{In}_{0.088}\text{Ir}_4\text{Sb}_{11.04}$ .

All known skutterudite systems report filler ions in the  $2a$  position, center of the

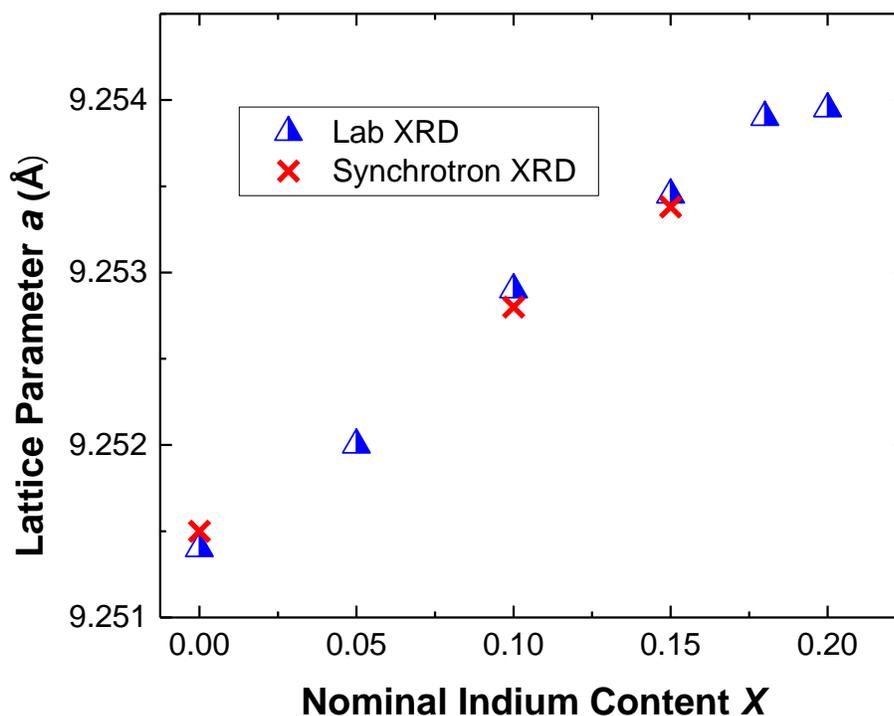

Figure 9.3: Cubic cell edge  $a$  vs nominal indium content  $x$  in  $\text{In}_x\text{Ir}_4\text{Sb}_{12}$ .

void site [225, 226, 230, 232, 233, 237, 247, 248]. Our refinement of indium in the  $2a$  position was unsuccessful as the occupancy refined to zero with unrealistic thermal parameters. Nonetheless moving indium along the [111] direction to the adjacent  $16f$  site resulted in reasonable values for the refined occupancy and isotropic  $U_{iso}$ . The displacement of indium from the ideal  $2a$  site is  $\leq 1.15 \text{ \AA}$ . Indium occupation of the void site was confirmed by its extremely large thermal displacement parameter as compared to Ir and Sb. The magnitude of  $U_{iso}$  for indium at room temperature

a) Synchrotron data collected at APS 11bm beamline,  $\lambda = 0.412731$  Å.

b) Crystal structure refined in space group  $Im\bar{3}$  with Ir at  $8c$  ( $\frac{1}{4}, \frac{1}{4}, \frac{1}{4}$ ), In at  $16f$  ( $x, x, x$ ) and Sb at  $24g$  ( $0, y, z$ ) sites, respectively.

is about ten times larger than that at 100 K due to exaggerated thermal motion at higher temperatures. The isotropic thermal parameter of Ir was found to be smaller as compared to Sb, consistent with other skutterudite systems. Iridium site ( $8c$ ) is fully occupied with no detectable vacancies observed for IrSb<sub>3</sub> and In<sub>0.1</sub>Ir<sub>4</sub>Sb<sub>12</sub> nominal samples. Antimony occupancy refinements, however, always show  $\sim 8\%$  vacancy at  $24g$  site (Table 9.1). Attempts of refining the structure by including antimony in other available crystallographic positions were not successful, and no

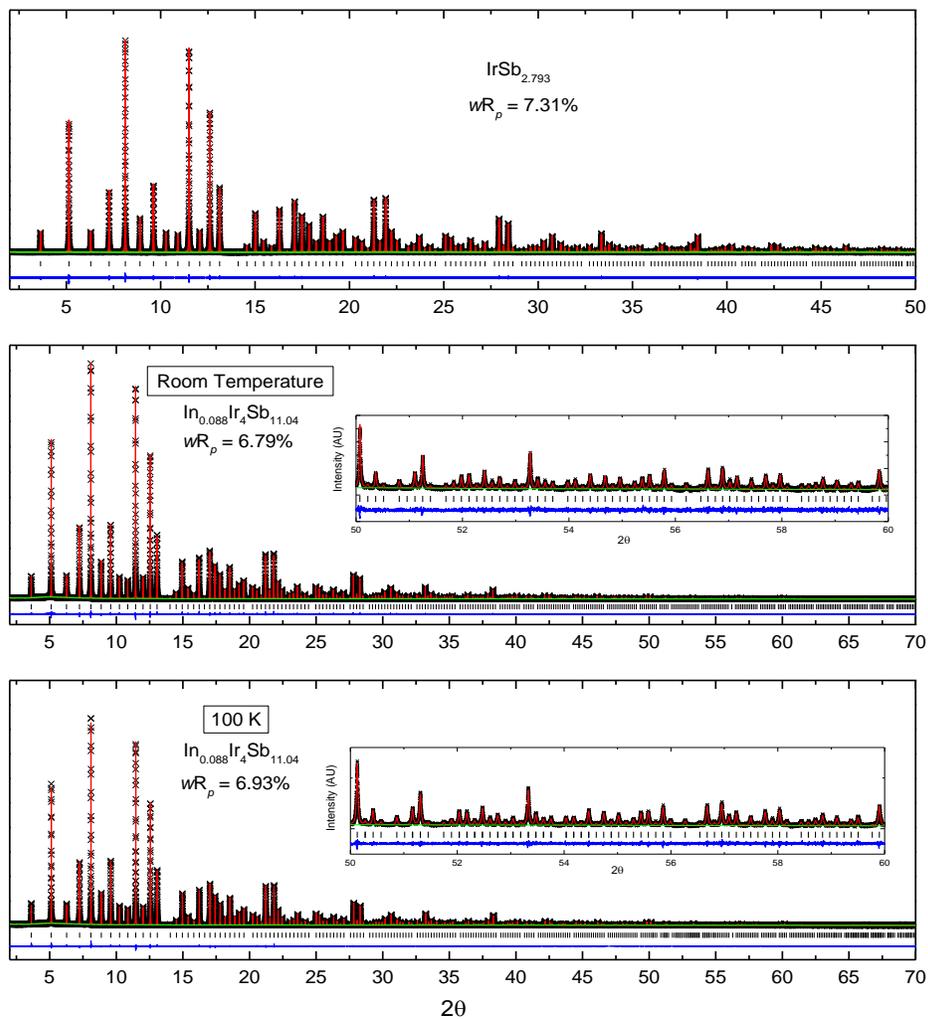

Figure 9.4: Synchrotron Rietveld refinement of nominal compositions IrSb<sub>3</sub> (top) and In<sub>0.1</sub>Ir<sub>4</sub>Sb<sub>12</sub> at room temperature (middle) and  $T = 100$  K (bottom) ( $\lambda = 0.412731$  Å). Observed (black crosses) and calculated (solid red line) profiles, background (green), and difference curve ( $I_{obs} - I_{calc}$ ) (blue) are shown for each refinement. The vertical bars indicate the expected reflection positions. Resulting stoichiometric identities and  $wR_p$  are represented.

indium was found at Ir site.

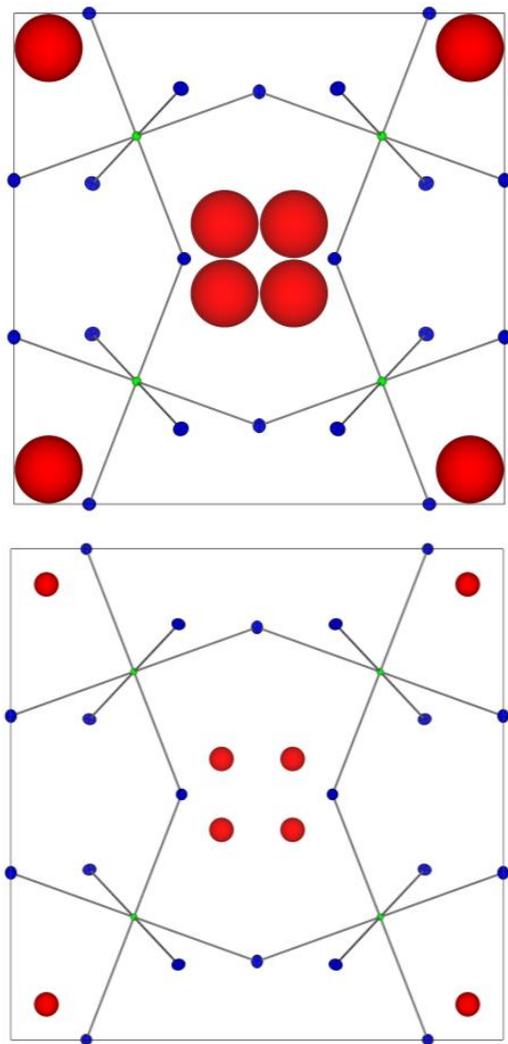

Figure 9.5: The  $\text{In}_{0.088}\text{Ir}_4\text{Sb}_{11.04}$  unit cell illustrated down the  $c$ -axis from room temperature (top) and 100 K (bottom) synchrotron XRD refinements with iridium, antimony, and indium thermal ellipsoids as green, blue, and red respectively.

There are few reported systems with antimony vacancies [249, 250] and we acknowledge that  $\sim 8\%$  vacancy is greater than such reported systems. This in part could be explained on the synthesis as antimony vapor was used to account for antimony loss in the sample and/or the covalency of iridium-antimony to allow chemical stability despite the slight reduction in the Zintl electron count. The uncommon movement of indium away from the center of the void site is likely associated with the resulting asymmetric bonding environment induced by Sb vacancies as well as the larger void size due to Ir. The influence of indium incorporation on cell dimensions, bond distances and angles are not significant.

### 9.3.2 Electrical Properties

Temperature dependent Resistivity measurements and Seebeck measurements of  $\text{In}_x\text{Ir}_4\text{Sb}_{12}$  ( $0 \leq x \leq 0.2$ ) from 300-600 Kelvin are shown in Figure 9.6 and Figure 9.7. Unfilled  $\text{IrSb}_3$  is metallic [234, 235, 251], and indium filled  $\text{In}_x\text{Ir}_4\text{Sb}_{12}$  samples are semiconductors (Figure 9.6). The activation energies ( $E_a$ ) for each sample were extracted using  $\sigma = \sigma_0 \exp(E_a/k_B T)$  and are listed in Table 9.2.

Table 9.2: Activation energy for  $\text{In}_x\text{Ir}_4\text{Sb}_{12}$ .

$x$	$E_a$ (meV)
0.05	218.6
0.1	216.6
0.15	106.8
0.18	105.8
0.2	91.8

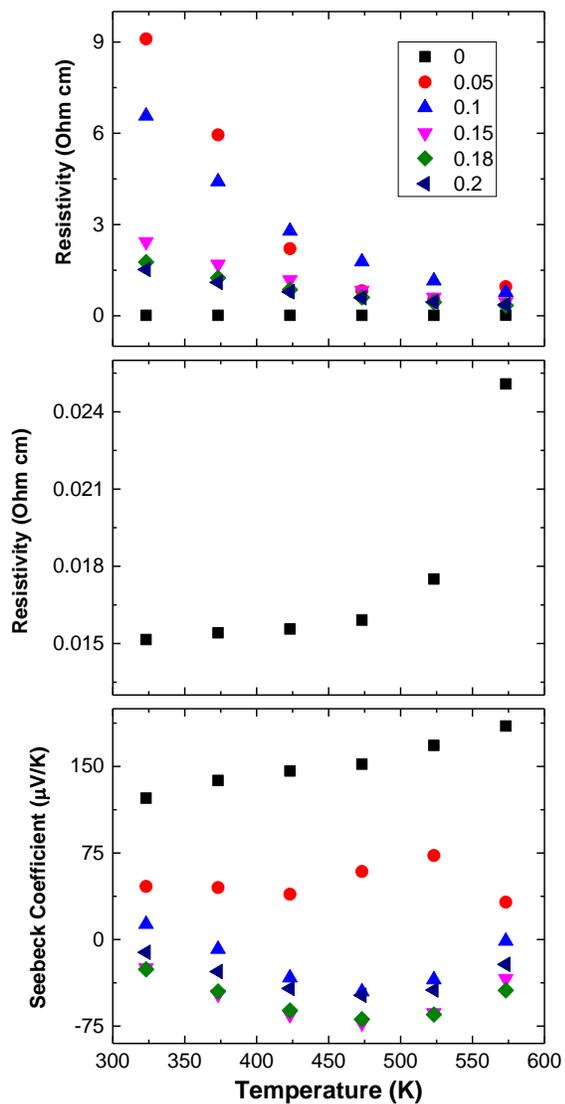

Figure 9.6: Temperature dependent resistivity (top/middle) and Seebeck coefficient data (bottom) of  $\text{In}_x\text{Ir}_4\text{Sb}_{12}$  samples ( $0 \leq x \leq 0.2$ ) from 300 to 600 K.

As indicated by the Resistivity measurements (Figures 9.6 and 9.7), from  $x = 0.05$  to  $0.2$ , a decrease in  $E_a$  is observed. With increasing indium content,  $\text{In}_x\text{Ir}_4\text{Sb}_{12}$  samples undergo a transition from primarily  $p$ -type to  $n$ -type semiconductors (Figure 9.6). These trends are in parallel with published work on unfilled  $\text{IrSb}_3$  and lanthanum filled  $\text{La}_x\text{Ir}_4\text{Sb}_{12}$  [234–236]. Because of the smaller void-site radius of  $\text{In}_x\text{Co}_4\text{Sb}_{12}$  relative to  $\text{In}_x\text{Ir}_4\text{Sb}_{12}$ , the indium contribution to the charge carrier in  $\text{In}_x\text{Ir}_4\text{Sb}_{12}$  should be insignificant compared to  $\text{In}_x\text{Co}_4\text{Sb}_{12}$  [232]. Contrary to  $\text{In}_x\text{Rh}_4\text{Sb}_{12}$  [237] an increase in indium content reveals a distinct trend in the Seebeck measurements for  $\text{In}_x\text{Ir}_4\text{Sb}_{12}$ .

Temperature dependent thermal conductivity data of  $\text{In}_x\text{Ir}_4\text{Sb}_{12}$  ( $0 \leq x \leq 0.2$ ) from 300-600 K are shown in Figure 9.8. The lattice thermal conductivity was calculated from  $K_l = K_t - K_e$ , where  $K_t$  is the total thermal conductivity and  $K_e$  is the electronic thermal conductivity. The electronic thermal conductivities were determined using the Wiedemann-Franz law,  $K_e = L\sigma T$ , where the Lorentz number,  $L$ , of  $2.00 \times 10^8 \text{ V}^2 \text{ K}^2$  was used [232, 237]. For all  $\text{In}_x\text{Ir}_4\text{Sb}_{12}$  samples, both the total and the lattice component of the thermal conductivity decrease with increasing temperature. With increasing indium content, the thermal conductivity decreases (Figure 9.8), consistent with indium filled  $\text{In}_x\text{Rh}_4\text{Sb}_{12}$  [237] and with the recognized presumption of the “rattling effect”. From  $x = 0$  to  $x = 0.2$ ,  $K_t$  decreases approximately 30% across temperature range, similar to  $\text{La}_x\text{Ir}_4\text{Sb}_{12}$  and  $\text{In}_x\text{Rh}_4\text{Sb}_{12}$  [235, 237]. For  $\text{In}_x\text{Rh}_4\text{Sb}_{12}$ , at higher temperatures, thermal conductivity becomes independent of indium content. This is attributed to the contribution of bipolar thermal diffusion ( $k_{BP}$ ) [237].

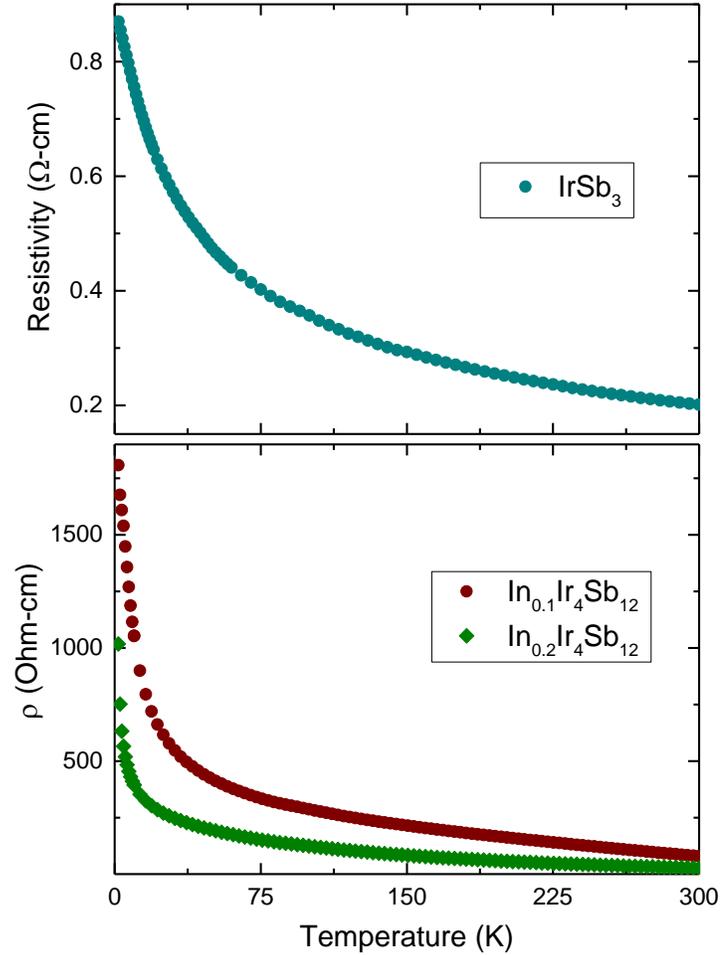

Figure 9.7: Temperature dependent, low temperature resistivity plots for  $\text{In}_x\text{Ir}_4\text{Sb}_{12}$  samples ( $x = 0, 0.1, \text{ and } 0.2$ ).

Conversely, effect of  $k_{BP}$  is not obvious for indium filled  $\text{In}_x\text{Ir}_4\text{Sb}_{12}$  ( $0 \leq x \leq 0.2$ ) within 300-600 K temperature range. Bipolar thermal diffusion typically occurs in lightly doped small band-gap semiconductors and when there is reasonable

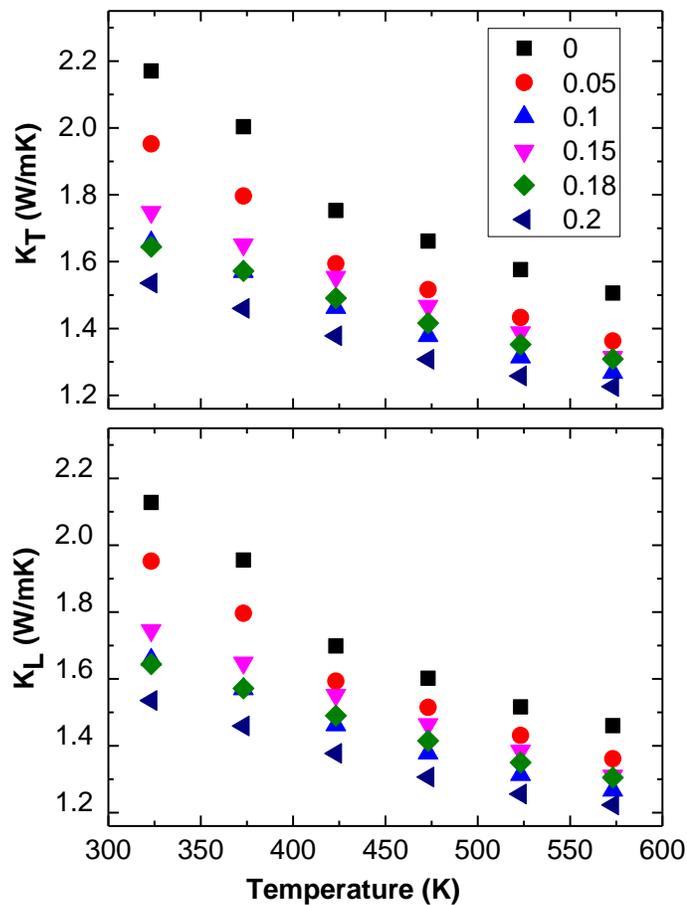

Figure 9.8: Temperature dependent total (top) and lattice thermal conductivity (bottom) of  $\text{In}_x\text{Ir}_4\text{Sb}_{12}$  samples ( $0 \leq x \leq 0.2$ ) from 300 to 600 K.

contribution to the total electrical conductivity by both charge carriers [252, 253]. Though the Seebeck properties (Figure 9.6) would perhaps indicate the possibility of slight  $k_{BP}$  contribution at higher temperatures, higher resistivity relative to  $\text{In}_x\text{Rh}_4\text{Sb}_{12}$  would suggest otherwise. For  $\text{In}_x\text{Rh}_4\text{Sb}_{12}$ , contribution of  $k_{BP}$  was

in part attributed to the disparity between hole and electron mobility [237]. It is known that large spin-orbit interaction influences electron and hole transport properties [254]. Zero-Field cooled magnetic susceptibility  $\chi(T)$  was measured for  $\text{In}_x\text{Ir}_4\text{Sb}_{12}$  ( $x = 0$  and  $0.2$  shown) (Figure 9.9). For all samples,  $\chi(T)$  is small and nearly temperature independent above 50 K. Unfilled  $\text{IrSb}_3$  exhibits diamagnetic behavior (consistent with Larmor diamagnetism), with the exception of a weak “Curie tail” at low temperatures due to the common presence of impurity spins (Figure 9.9) [255, 256]. A group 9 metal for an unfilled  $\text{BX}_3$  skutterudite has a +3 charge, and therefore an electronic configuration of  $nd^6$  [255]. Thus, for unfilled  $\text{IrSb}_3$  ( $\text{Ir}^{3+}$  - filled  $t_{2g}$  band and an empty  $e_g$  band), diamagnetic behavior is undisputed.

With the increase of indium, below 50 K, the magnetic susceptibility appears temperature dependent (Figure 9.9). It could be argued that small inclusions of defect free spin 1/2 Ir ions could explain the magnetic susceptibility below  $\sim 50$  K for  $\text{In}_{0.2}\text{Ir}_4\text{Sb}_{12}$ . This was suggested for  $\text{In}_x\text{Rh}_4\text{Sb}_{12}$  [256]. It is possible that the observed increase in  $\chi(T)$  (compared to  $\text{In}_x\text{Rh}_4\text{Sb}_{12}$  [256]) cannot be attributed alone to the small presence of defect spin 1/2 Ir ions. In addition, because of the on-site coulomb repulsion energy for  $5d$  transition metals compared to  $4d$  transition metals [257], iridium charge modification is conceivable. Temperature dependent thermoelectric figure of merit,  $ZT$ , values of  $\text{In}_x\text{Ir}_4\text{Sb}_{12}$  samples ( $0 \leq x \leq 0.2$ ) are revealed in Figure 9.10. Though there is a decrease in total thermal conductivity with increasing indium content, the corresponding large increase in resistivity outweighs the prior and thus dictates the thermoelectric figure of merit,  $ZT$ . For

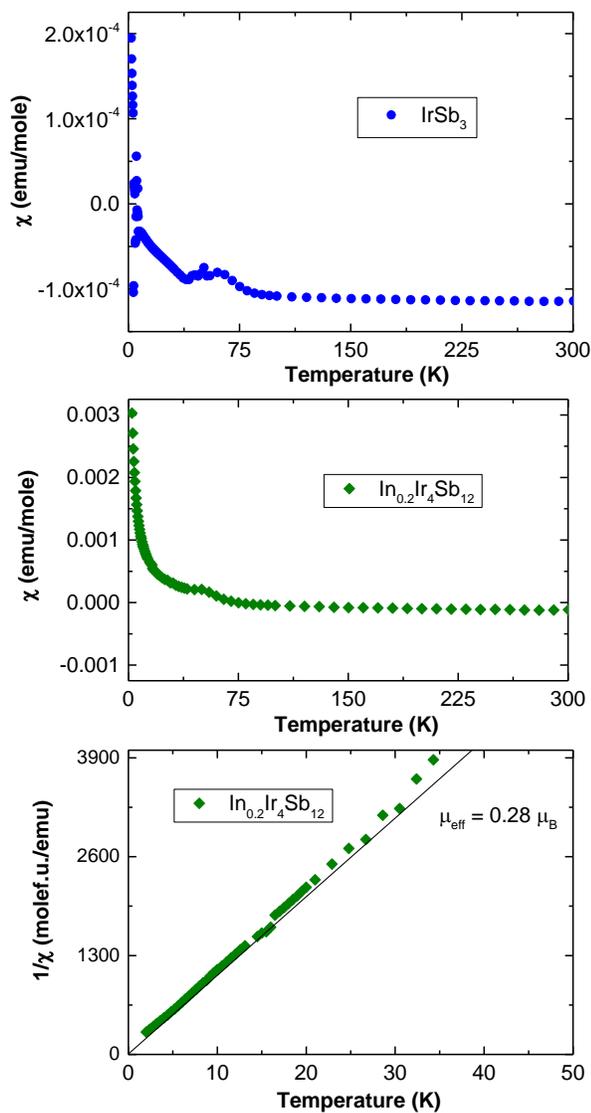

Figure 9.9: Zero-Field cooled magnetic susceptibility plots for  $\text{In}_x\text{Ir}_4\text{Sb}_{12}$  ( $x = 0$  and 0.2) and inverse magnetic susceptibility plot for  $\text{In}_x\text{Ir}_4\text{Sb}_{12}$  ( $x = 0.2$ ).

$\text{In}_x\text{Rh}_4\text{Sb}_{12}$ , increase in electrical resistivity also outweighs the corresponding decrease in total thermal conductivity, revealing an overall decrease in ZT [237]. The observed decrease in ZT for  $\text{In}_x\text{Rh}_4\text{Sb}_{12}$ , however, is not as severe ( $\sim 10$  fold decrease). This is not the case for  $\text{In}_x\text{Co}_4\text{Sb}_{12}$  and other light-element filling skutterudite systems have been proven to enhance TE performance by improving electrical transport properties and decreasing the total thermal conductivity [232, 258–261]. As thermoelectric properties of semiconductors are closely related to their electronic band structure, it is likely the large increase in resistivity can be explained by the electronic structure in relation to the contiguity of the  $16f$  indium occupying the relatively large icosahedron. Electronic band structure studies of such indium filled  $\text{IrSb}_3$  are therefore warranted.

Table 9.3 reveals electrical and thermal values of  $\text{In}_x\text{M}_4\text{Sb}_{12}$ , ( $\text{M} = \text{Ir}, \text{Rh}$ , and  $\text{Co}$ ) at approximately 575 K for the  $x > 0$  sample possessing the highest ZT. The samples presented in Table 9.3 all had the same synthesis with similar pellet densities [232, 237].

Table 9.3:  $\text{In}_x\text{M}_4\text{Sb}_{12}$ , ( $\text{M} = \text{Ir}, \text{Rh}$ , or  $\text{Co}$ ) at approximately 575 K for  $x > 0$  sample possessing the highest ZT [158,163].

	$\text{In}_x\text{Ir}_4\text{Sb}_{12}$	$\text{In}_x\text{Rh}_4\text{Sb}_{12}$	$\text{In}_x\text{Co}_4\text{Sb}_{12}$
$x$	0.18	0.05	0.3
$R$ (Ohm cm)	0.341	$1.25 \times 10^{-3}$	$2.4 \times 10^{-3}$
$S$ (V/K)	-44	55	-267
$K_T$ (W/mK)	1.31	2.5	2.08
ZT	$2.42 \times 10^{-4}$	0.11	1.19
Reference		232	237

For  $\text{In}_{0.3}\text{Co}_4\text{Sb}_{12}$ , the ZT value is primarily attributed to the large negative

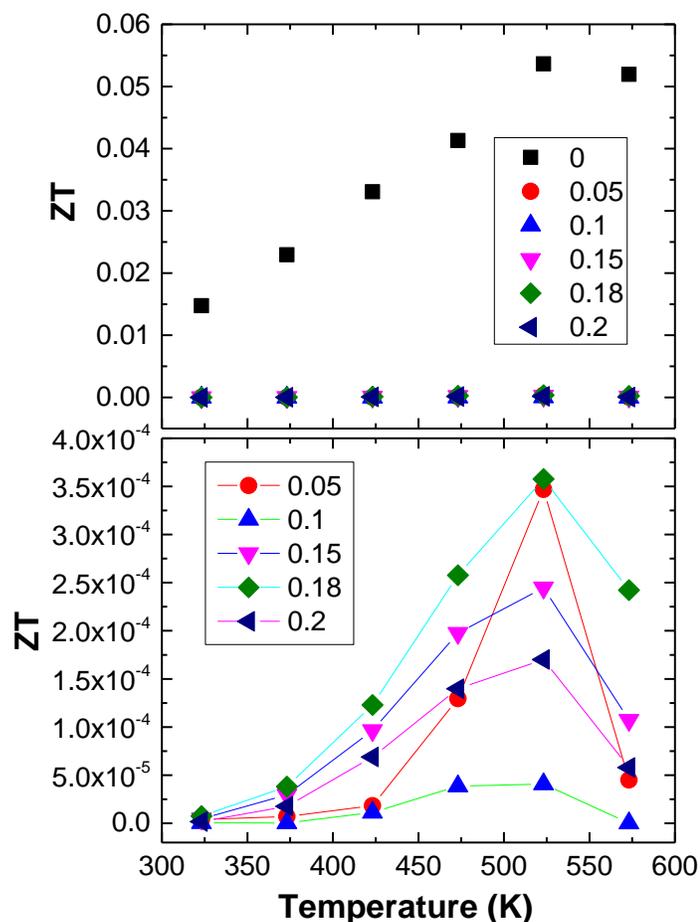

Figure 9.10: Resulting thermoelectric figure of merit,  $ZT$ , values of  $\text{In}_x\text{Ir}_4\text{Sb}_{12}$  samples ( $0 \leq x \leq 0.2$ ) shown from 300-600 K.

Seebeck coefficient. For  $\text{In}_x\text{Rh}_4\text{Sb}_{12}$ , though measured resistivity is desirable, large total thermal conductivity and small Seebeck coefficient characterize the insignificant  $ZT$  value. Of the three compared skutterudites,  $\text{In}_x\text{Ir}_4\text{Sb}_{12}$  samples reveal the smallest total thermal conductivity. For  $\text{In}_x\text{Co}_4\text{Sb}_{12}$ ,  $K_t$  increases with in-

creasing  $x$ , and as discussed previously,  $K_t$  for  $\text{In}_x\text{Rh}_4\text{Sb}_{12}$  becomes independent of indium content at higher temperature due to the contribution of bipolar thermal diffusion ( $k_{BP}$ ) [232,237]. From the ZT values alone (Figure 9.10),  $\text{In}_x\text{Ir}_4\text{Sb}_{12}$  skutterudite clearly is not a thermoelectric candidate. However, the effect of indium on decreasing the total thermal conductivity as well as possible spin-orbit coupling effects of iridium on electronic and thermal parameters suggest indium filled iridium-rhodium-cobalt antimony alloy-based skutterudite system as a fundamentally intriguing research avenue.

#### 9.4 Investigation of Indium Filled Rhodium-Iridium-Antimonide Skutterudites

Indium filled  $\text{In}_x\text{Rh}_{4-y}\text{Co}_y\text{Sb}_{12}$  for  $x = 0$  and  $0.1$  has been investigated [262]. For  $\text{In}_{0.1}\text{Rh}_{4-y}\text{Co}_y\text{Sb}_{12}$ , the increased thermal conductivity combined with diminishing Seebeck coefficients at elevated temperatures results in ZT values much lower than indium-filled  $\text{In}_{0.1}\text{Co}_4\text{Sb}_{12}$  sample. However, for unfilled  $\text{Co}_{4-y}\text{Rh}_y\text{Sb}_{12}$ , ZT increases with increasing rhodium content. While rhodium substitution reduces the thermal conductivity of unfilled compositions, indium-filled samples exhibit bipolar thermal conductivity with increasing rhodium content [262]. Thermal and electrical properties of  $\text{In}_{0.15}\text{Ir}_{4-y}\text{Rh}_y\text{Sb}_{12}$  ( $y = 0, 1, 2, 3,$  and  $4$ ) are compared in Figure 9.11 and 9.12.

As discussed, for  $\text{In}_x\text{Rh}_4\text{Sb}_{12}$ , although measured resistivity is desirable, large total thermal conductivity and small Seebeck coefficient characterize the insignif-

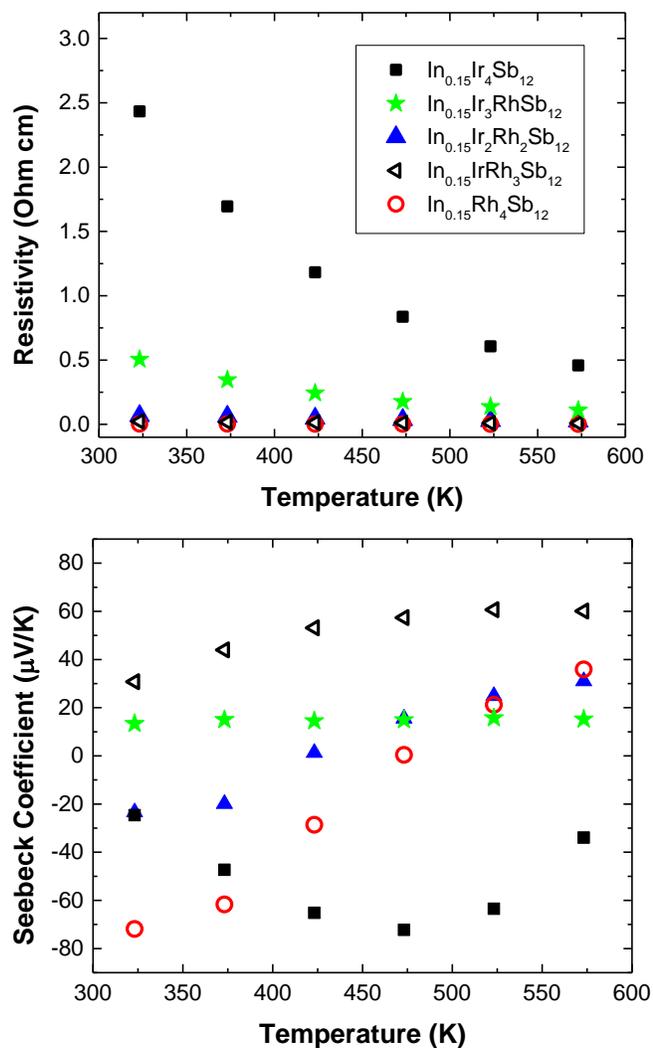

Figure 9.11: Temperature dependent resistivity (top) and Seebeck coefficient data (bottom) of  $\text{In}_{0.15}\text{Ir}_{4-y}\text{Rh}_y\text{Sb}_{12}$  samples ( $0 \leq y \leq 1$ ) from 300 to 600 K.

inant ZT value and  $\text{In}_x\text{Ir}_4\text{Sb}_{12}$  samples reveal the smallest total thermal conductivity relative to Co and Rh versions (Table 9.3). With increasing  $y$  for

$\text{In}_{0.15}\text{Ir}_{4-y}\text{Rh}_y\text{Sb}_{12}$ , resistivity dramatically decreases. The total thermal conductivity remains small for nearly all  $\text{In}_{0.15}\text{Ir}_{4-y}\text{Rh}_y\text{Sb}_{12}$  (with the exception of  $\text{In}_{0.15}\text{Rh}_4\text{Sb}_{12}$ ) (Figure 9.12). For  $\text{In}_{0.15}\text{Ir}_2\text{Rh}_2\text{Sb}_{12}$ , the Seebeck coefficient and resistivity are both similar to  $\text{In}_{0.15}\text{Rh}_4\text{Sb}_{12}$ , and the total thermal conductivity equates to  $\text{In}_{0.15}\text{Ir}_4\text{Sb}_{12}$ , resulting in  $ZT$  approximately three times greater than  $\text{In}_{0.15}\text{Rh}_4\text{Sb}_{12}$  at higher temperatures (Figure 9.12). Yet, because the magnitude of the Seebeck remains small compared to  $\text{In}_x\text{Co}_4\text{Sb}_{12}$  [9], a high  $ZT$  is not obtained.

Because  $\text{IrSb}_3$  cell parameter is larger than  $\text{RhSb}_3$  [237], it is conceivable a larger void site for the same filler atom would enhance dampening of the lattice thermal conductivity. This prediction is observed when comparing the total thermal conductivities of  $\text{In}_{0.1}\text{Ir}_4\text{Sb}_{12}$  and  $\text{In}_{0.1}\text{Rh}_4\text{Sb}_{12}$  (Figure 9.12). The trends shown in Figures 9.11 and 9.12 reveal that the electrical and thermal properties can be tuned for  $\text{In}_{0.15}\text{Ir}_{4-y}\text{Rh}_y\text{Sb}_{12}$  mirroring the behavior of  $\text{In}_{0.15}\text{Rh}_4\text{Sb}_{12}$  ( $y < 0.5$ ) or  $\text{In}_{0.15}\text{Ir}_4\text{Sb}_{12}$  ( $y < 0.5$ ). A solid solution of iridium, rhodium, and cobalt was investigated, however, synthesizing samples under similar conditions resulted in separate Ir/Rh and Co skutterudite phases.

## 9.5 Summary

The work presented on indium filled  $\text{In}_x\text{Ir}_4\text{Sb}_{12}$  skutterudites highlights trends in key thermoelectric properties that are atypical to the “phonon-glass/electron-crystal” approach. Unlike known “rattler” filled skutterudites which show an increase in  $ZT$  with increasing “rattler” concentration, a substantial decrease in  $ZT$

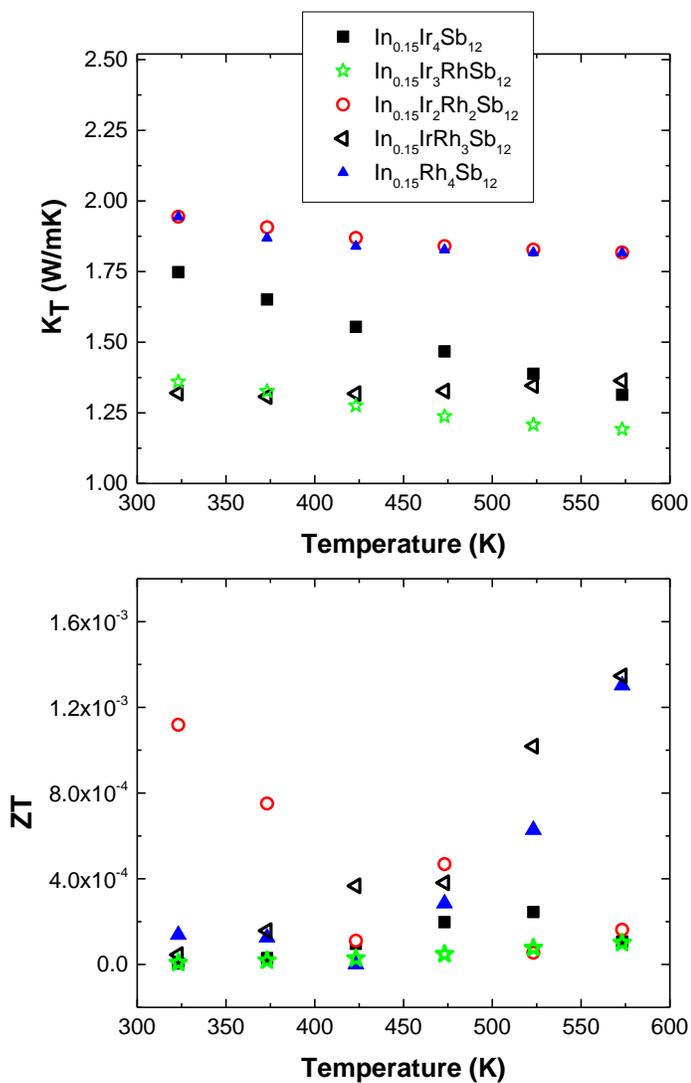

Figure 9.12: Temperature dependent total thermal conductivity (top) and resulting thermoelectric figure of merit,  $ZT$ , values of  $\text{In}_{0.15}\text{Ir}_{4-y}\text{Rh}_y\text{Sb}_{12}$  samples ( $0 \leq y \leq 1$ ) (bottom) from 300 to 600 K.

with addition of indium is observed. This is credited to the substantial increase in electrical resistivity and decrease in the Seebeck coefficient with indium con-

tent. Synchrotron X-ray diffraction refinements reveal  $\sim 8\%$  antimony vacancy and indium partially occupying the  $16f$  site. As thermoelectric properties of semiconductors are closely related to their electronic band structure, it is likely the large increase in resistivity can be explained by the electronic structure in relation to indium occupying the  $16f$  position in the large icosahedron void site and/or antimony vacancies. Electronic band structure studies and further structure and thermoelectric property analysis of indium filled  $\text{IrSb}_3$  under high pressure synthesis conditions are therefore warranted.

## 9.6 Methods

### 9.6.1 Synthesis

Polycrystalline samples of  $\text{In}_x\text{Ir}_4\text{Sb}_{12}$  ( $0 \leq x \leq 0.2$ ) were prepared by standard solid-state reaction. The elements 99.999% In powder (Aldrich), 99.5% Ir powder (Aldrich), and 99.9% Sb powder (Strem) were thoroughly mixed in air in an agate mortar. The powders were loaded into alumina crucibles and reacted in a tube furnace at  $610^\circ\text{C}$  for 4 h under a constant flow of antimony vapor and 95/5  $\text{N}_2/\text{H}_2$  gas. The samples were then ground and light-pressed into 10 mm diameter pellets and conventionally sintered at  $610^\circ\text{C}$  for 4 h, followed by  $675^\circ\text{C}$  for 4 h under a constant flow of 95/5  $\text{N}_2/\text{H}_2$  gas. The resultant sintered pellets were approximately 65% of the theoretical density.

### 9.6.2 Structure Determination

Phase analysis of powder samples was performed by X-ray diffraction using a Rigaku MiniFlex II diffractometer with Cu  $K_\alpha$  radiation and a graphite monochromator for the diffracted beam. Lattice parameters were calculated by LeBail fit using KCl ( $Fm\bar{3}m$ ) as an internal standard. Synchrotron X-ray Diffraction (Advanced Photon Source 11-BM) was collected for  $\text{In}_x\text{Ir}_4\text{Sb}_{12}$  ( $x = 0, 0.1, \text{ and } 0.15$ ) samples at room temperature ( $\lambda=0.412731 \text{ \AA}$ ,  $2\theta \leq 50$ ) along with  $T = 100 \text{ K}$  for  $x = 0.1$  sample ( $2\theta \leq 70$ ).

### 9.6.3 Electrical Properties

The principal thermoelectric properties; the Seebeck coefficient ( $S$ ) electrical conductivity ( $\sigma$ ) and thermal conductivity ( $K$ ) were measured from 300-600 K. The Seebeck coefficient and electrical conductivity data was collected on an ULVAC ZEM-3 under a helium atmosphere. Thermal diffusivity ( $\alpha$ ) was measured on a Netzsch LFA 457 Micro Flash under flowing  $\text{N}_2$ . Low-temperature (2-300 K) magnetization measurements were obtained with a Quantum Design MPMS and resistivity (50-300 K) measurements were obtained using a Quantum Design PPMS.

## APPENDICES

## Appendix A: Charge Transfer Instability in a Mixed Ir/Rh Honeycomb Lattice in $\text{Li}_2\text{Ir}_{1-x}\text{Rh}_x\text{O}_3$ Solid Solution

### A.1 Abstract

The solid solution series  $\text{Li}_2\text{Ir}_{1-x}\text{Rh}_x\text{O}_3$  is synthesized for several values of  $x$  between 0 and 1. The compounds possess a monoclinic layered structure (space group  $C2/m$ ) throughout the solid solution range with the lattice constants following Vegard's relationship. Magnetization and resistivity data below room temperature are presented. The effective magnetic moment ( $\mu_{eff}$ ) is reduced below the value obtained by interpolating between the end-members, presumably due to nearest neighbor charge exchange leading to non-magnetic  $\text{Ir}^{5+}/\text{Rh}^{3+}$  pairs. Surprisingly, the degree of reduction of  $\mu_{eff}$  cannot be explained by a random mixture of Ir and Rh and, in particular, is strongly asymmetric around  $x = 0.5$ . This anomalous moment reduction possibly results from the difference in on-site Coulomb repulsion between Ir and Rh ions.

## A.2 Introduction

With the prospect of new science and technology in topological insulators, systems with strong spin-orbit coupling (SOC) are of great interest within the solid state science community. Through numerous studies, strong SOC systems have been shown to exhibit many unconventional properties that challenge existing theory. In particular, many  $A_2MO_3$  “honeycomb” layered oxides where A is an alkali atom and M is a 4d or 5d element, show unique electronic and magnetic properties indicative of SOC [1-10]. These properties also reflect the lamellar structure, composed of alternating layers of pure Li and mixed  $LiM_2$  units in a cubic-close-packed oxide array [11]. The  $LiM_2$  layers are composed of a hexagonal network of edge sharing  $MO_6$  octahedra where a single  $Li^+$  ion occupies the centers of the resulting hexagons (Figure A.1).

The honeycomb lattice iridates  $A_2IrO_3$  ( $A = Li, Na$ ) are especially important since Ir has the strongest SOC among magnetic d-electron elements and these materials have been proposed alternatively as candidates for either topologically insulating or Kitaev quantum spin liquid states [12,13]. For  $Li_2IrO_3$ , three different polytypes are known. In  $\alpha$ - $Li_2IrO_3$ , edge-sharing  $IrO_6$  octahedra form a simple two-dimensional (2D) honeycomb layered structure [11]. For  $\beta$ - and  $\gamma$ - $Li_2IrO_3$ , however, the edge shared  $IrO_6$  octahedra form three dimensional (3D) connected arrangement [14,15]. Specifically, these  $Li_2MO_3$  polytypes are  $Li_2MnO_3$ -type ( $C2/m$ ) and  $Li_2SnO_3$ -type ( $C2/c$ ) with the difference being the stacking of the  $LiM_2$  layers along the  $c$ -axis (Figure A.2) [16]. There has been some controversy in the lit-

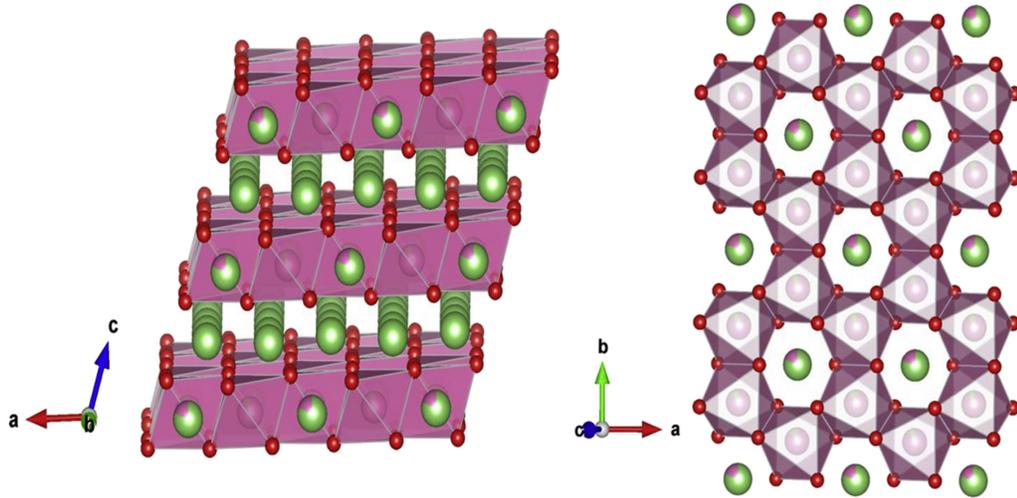

Figure A.1: (a)  $\text{Li}_2\text{MO}_3$  ( $M = \text{Ir}, \text{Rh}$ ) structure as alternating layers of  $\text{Li}^+$  and  $\text{LiM}_2$  and (b)  $\text{LiM}_2$  layer where  $\text{MO}_6$  octahedra form the honeycomb like lattice. Green, pink and red spheres represent lithium, metal, and oxygen atoms respectively.

erature regarding the space group of  $\text{Li}_2\text{IrO}_3$ , particularly between  $C2/c$  ( $Z = 8$ ) symmetry or  $C2/m$  ( $Z = 4$ ) symmetry [8,11]. Recent work, confirmed in the present study, shows that higher symmetry  $C2/m$  is the appropriate space group for  $\text{Li}_2\text{IrO}_3$  [11,17]. It is known that  $\text{Li}_2\text{IrO}_3$  is electrically insulating with an effective magnetic moment  $\mu_{eff} = 1.83 \mu_B$  and an antiferromagnetically ordered state below 15 K [17,18]. This behavior has been described as that of a Mott insulator with magnetism of a Heisenberg-Kitaev interaction arising from SOC [18]. The isoelectronic  $4d^5$  honeycomb compound  $\text{Li}_2\text{RhO}_3$  which crystallizes in the  $C2/m$  structure has been explored, and is also found to be an insulator [19,20]. Long range magnetic order was not observed in this system but the susceptibility displays a frequency-dependent feature consistent with a spin glass state below a

freezing temperature,  $T_f = 5$  K [21]. Since the Weiss temperature,  $\theta_W$ , is 50K, the ratio  $\theta_W/T_f$  of roughly 10 suggests strong geometrical frustration, although the presence of stacking faults, discussed below introduces a random component to the mean field. While the isoelectronic and isostructural honeycomb iridates and rhodates are both insulators, the analogous comparison of the square-lattice systems  $\text{Sr}_2\text{IrO}_4$  and  $\text{Sr}_2\text{RhO}_4$ , shows a transition from insulating to metallic ground state [22,23]. The absence of such a transition in the honeycomb systems has been suggested to result from the combined effect of (i) quasi-molecular orbitals, which effect a band insulator, and (ii) the interplay between SOC and Coulomb correlations [20]. An important difference between the Ir and Rh honeycomb systems is a change of  $\mu_{eff}$ , from  $1.83 \mu_B$  in the large-SOC  $\text{Li}_2\text{IrO}_3$  [18] to  $2.2 \mu_B$  in  $\text{Li}_2\text{RhO}_3$  [20]. In the present work, we study the solid solution series  $\text{Li}_2\text{Ir}_{1-x}\text{Rh}_x\text{O}_3$ , in particular to examine the change in both  $\mu_{eff}$  as well as charge transport across the series. We find a strong moment reduction on the Rh-rich side of the series, which supports the notion that on-site Coulomb energy in the Rh-rich compounds plays an important role in charge localization.

### A.3 Experimental

Polycrystalline samples of  $\text{Li}_2\text{Ir}_{1-x}\text{Rh}_x\text{O}_3$  ( $x = 0, 0.2, 0.4, 0.5, 0.6, 0.8$  and  $1$ ) were prepared by intimately mixing and grinding stoichiometric amounts of  $\text{Li}_2\text{CO}_3$  (Sigma, 99.8%),  $\text{IrO}_2$  and  $\text{Rh}_2\text{O}_3$  (Matthey, 99.99%) in an agate mortar. The  $\text{Li}_2\text{CO}_3$  was dried at 120 C overnight, and the  $\text{IrO}_2$  was obtained by decomposing

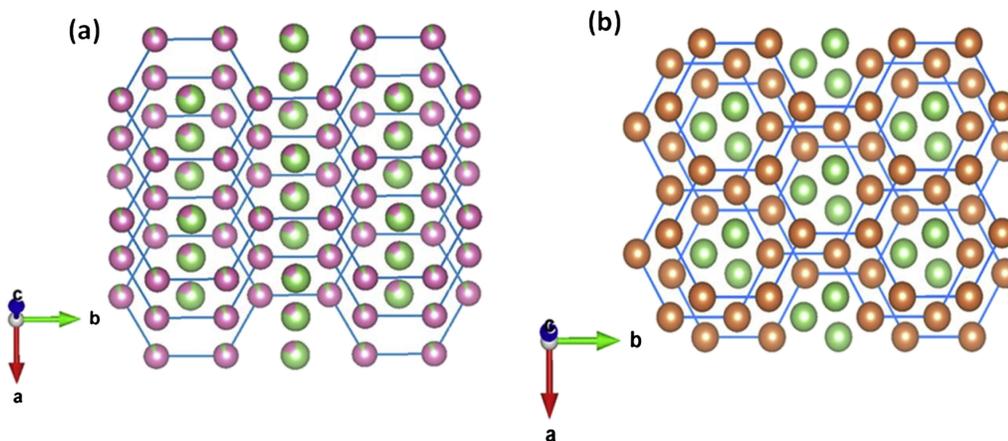

Figure A.2: Stacking of  $\text{LiM}_2$  layers in (a)  $\text{Li}_2\text{MnO}_3$ -type ( $C2/m$ ) and (b)  $\text{Li}_2\text{SnO}_3$ -type ( $C2/c$ ) structure when viewed along the  $c$ -axis. Green, purple and orange spheres represent lithium, manganese and tin atoms respectively. Oxygen atoms are omitted for clarity.

$\text{IrCl}_3$  (Alfa Aesar, 99.9%) at 750 C for 10 h under air flow. For all synthesis processes, 5% excess  $\text{Li}_2\text{CO}_3$  was added to compensate for high temperature lithium volatility. The samples were then pelletized and sintered in oxygen flow at 950 C for 24 h for all samples except  $\text{Li}_2\text{RhO}_3$  which was sintered at 850 C for 24 h with intermittent grinding. All samples were black in color. X-ray diffraction (XRD) characterization was done on a Rigaku Miniflex II diffractometer using  $\text{Cu K}\alpha$  radiation and a graphite monochromator. Seebeck and resistivity measurements were performed at high temperatures (300–800 K) on an ULVACRIKO ZEM 3 under a static helium atmosphere. Low-temperature (5–300 K) magnetization measurements were obtained with a Quantum Design MPMS and resistivity (50–300 K) measurements were obtained using a Quantum Design PPMS.

## A.4 Results and Discussion

### A.4.1 Structural Properties

Polycrystalline samples of complete solid solution between  $\text{Li}_2\text{IrO}_3$  and  $\text{Li}_2\text{RhO}_3$  were successfully synthesized. Figure A.3(a) shows the XRD patterns of the samples crystallizing in monoclinic layered structure with space group  $C2/m$ . The  $a$ -,  $b$ - and  $c$ -lattice parameters decrease marginally with increasing  $x$  in  $\text{Li}_2\text{Ir}_{1-x}\text{Rh}_x\text{O}_3$  as shown in Figure A.3(b). This trend is expected given the small difference in ionic radii between  $\text{Ir}^{4+}$  (0.625) and  $\text{Rh}^{4+}$  (0.60) [24]. Figure A.4(a,b) shows changes in the  $\beta$  angle and the unit cell volume as a function of  $x$ . It is noticed that the reflections in the XRD patterns are very weak between  $2\theta$  of  $19^\circ$  and  $33^\circ$ , a region where stacking faults affect the intensity of the hkl reflections and create an asymmetric broadening of the affected reflections. With the exception of  $\text{Li}_2\text{IrO}_3$ , the Le-Bail refinement clearly does not fit the broad asymmetrical peaks within the  $2\theta$  region  $19\text{--}33^\circ$  (Figure A.3).

Refining the Ir(4*g*)–Li(2*a*) site occupancies did not improve the fit to these asymmetric broad peaks [11]. The broadness of these peaks in this region for other honeycomb layered structures has been attributed also to the existence of stacking faults [16,25,26]. A structure with less peak broadening in the specific stacking fault  $2\theta$  region with an increase in temperature is observed for  $\text{Li}_2\text{IrO}_3$ , while the best structurally ordered sample was obtained at 850 C in oxygen atmosphere for  $\text{Li}_2\text{RhO}_3$ .

In order to evaluate the degree of stacking faults of  $\text{Li}_2\text{Ir}_{1-x}\text{Rh}_x\text{O}_3$  in a quan-

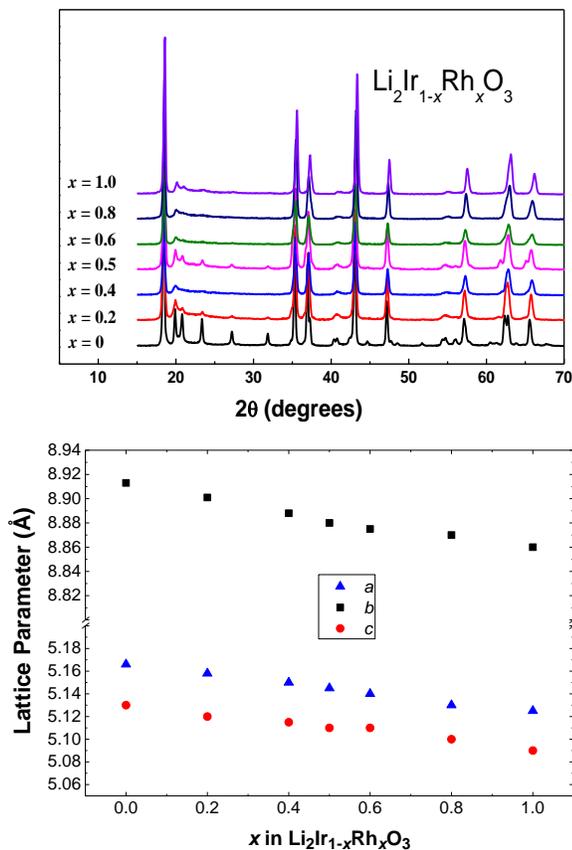

Figure A.3: (a) Powder XRD patterns and (b) lattice parameters for  $x=0-1$  in  $\text{Li}_2\text{Ir}_{1-x}\text{Rh}_x\text{O}_3$ .

titative manner, the DIFFaX software was employed [27] and a model similar to that used by Breger et al. was applied [16]. The DIFFaX software requires the cell axes to be defined such that the  $c$ -axis is perpendicular to the fault direction, resulting with a new idealized unit cell. Thus, a hexagonal unit cell with  $a_{hex}=a_{C2/m}$  and  $c_{hex}=c_{C2/m}\cos(\beta_{C2/m}-90)$  was implemented and individual honeycomb metal oxide layers were defined. As discussed by Breger et. al., in order to replicate

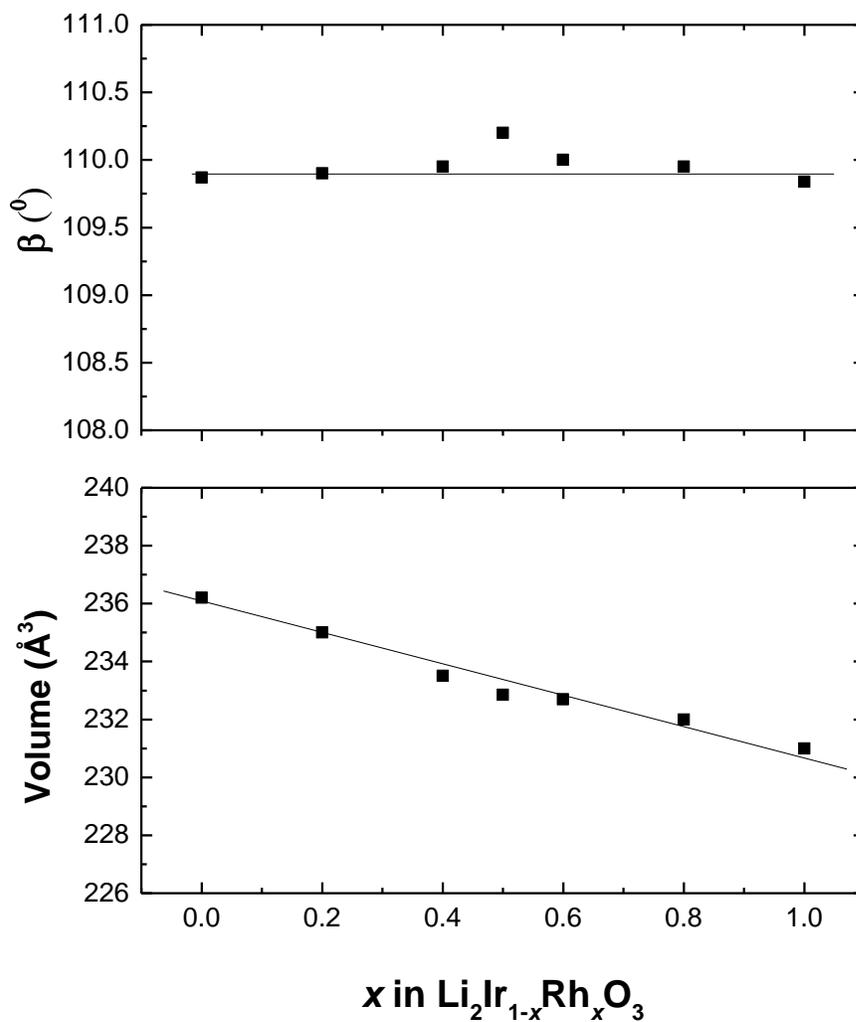

Figure A.4: (a) The  $\beta$  angle and (b) Cell volume as a function of  $x$  in  $\text{Li}_2\text{Ir}_{1-x}\text{Rh}_x\text{O}_3$ .

the  $\text{A}_1\text{B}_1\text{C}_1$  stacking sequence of  $\text{Li}_2\text{IrO}_3$  ( $C2/m$ ), the honeycomb metal oxide layers were characterized by the  $[1/3,0,1]$  transition vector ( $\alpha_1$ ). The rotation of the stacking direction by  $120^\circ$  and  $240^\circ$  was described by the transition vectors

$[2/3, 2/3, 1]$  and  $[0, 1/3, 1]$  ( $\alpha_2$  and  $\alpha_3$ ). Probabilities were assigned to each of the three transition vectors, with  $\alpha_1 + \alpha_2 + \alpha_3 = 1$ . For the latter two transition vectors, there was no tangible difference in the model when varying the contribution for a given total stacking fault probability. Thus for the models presented, the assumption  $\alpha_2 = \alpha_3$  was implemented. Figure A.5 reveals a comparison of XRD patterns in the  $2\theta$  region  $19\text{--}33^\circ$  among the different compounds  $\text{Li}_2\text{Ir}_{1-x}\text{Rh}_x\text{O}_3$  ( $x = 0, 0.5$  and  $1$ ) (blue line), along with simulated DIFFaX best fit XRD patterns with corresponding stacking fault percentages (red line). These simulated XRD patterns supports the conjecture that the asymmetrical broadness of the peaks is due to the presence of stacking faults. As expected, a higher density of stacking faults is estimated for the honeycomb  $\text{Li}_2\text{RhO}_3$  (30%) compared to  $\text{Li}_2\text{IrO}_3$  (5%).

#### A.4.2 Electrical Properties

The magnetic susceptibility  $\chi(T)$ , was measured for in a magnetic field of  $H = 0.5T$ . Both  $\text{Li}_2\text{IrO}_3$  and  $\text{Li}_2\text{RhO}_3$  display paramagnetic behavior above 50 K [8,21]. Figure A.6 shows the magnetic susceptibility for the series as function of temperature. The behavior of the end members is consistent with previous results that show deviations in Curie-Weiss behavior indicative of antiferromagnetic interaction at 15 K for  $\text{Li}_2\text{IrO}_3$  and spin freezing 6 K for  $\text{Li}_2\text{RhO}_3$  [18,21]. The inverse susceptibility,  $1/\chi(T)$  is fit by the Curie-Weiss form,  $\chi = C/(T - \theta) - \chi_{vv}$ , where  $C$  is the Curie constant,  $\theta$  is the Weiss constant and  $\chi_{vv}$  a van Vleck temperature independent term. The  $\mu_{eff}$ , values reported here were obtained by selecting, for each  $x$ , a

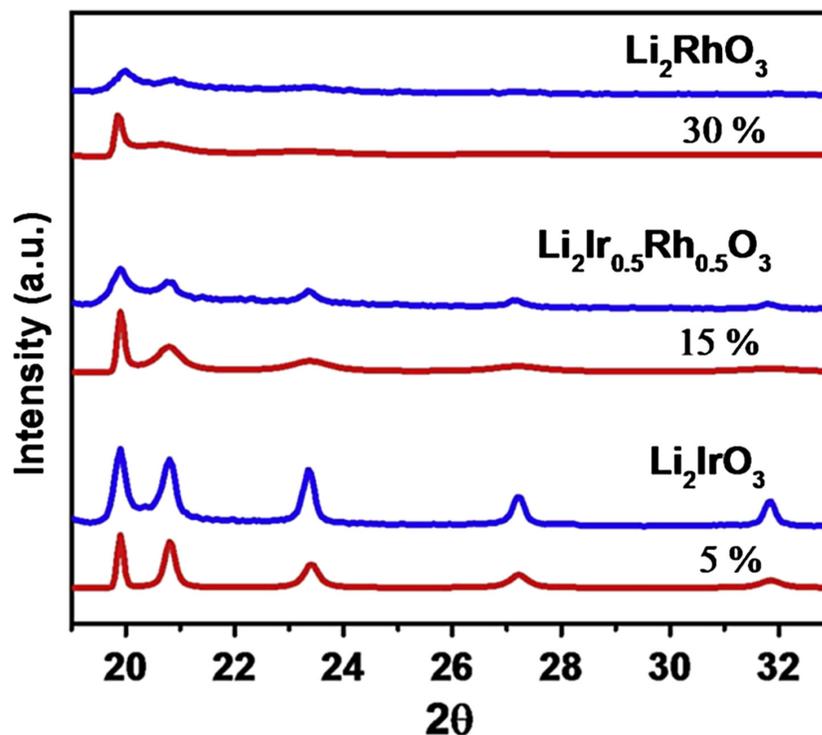

Figure A.5: DIFFaX simulated (red line) and experimental powder XRD patterns (blue line) for  $\text{Li}_2\text{Ir}_{1-x}\text{Rh}_x\text{O}_3$  ( $x = 0, 0.5$  and  $1.0$ ) in the region  $2\theta = 19\text{--}33^\circ$ .

$\chi_{vv}$  that provides the smallest sum of the variances ( $\chi^2$ ) for a linear fit to  $1/\chi(T)$ . Resulting fits between 100 and 300 K yields  $\mu_{eff}$  values of  $1.87\mu_B$  for  $\text{Li}_2\text{IrO}_3$  and  $2.03\mu_B$  for  $\text{Li}_2\text{RhO}_3$  (Figure A.6b). These values of  $\mu_{eff}$  are close to the expected spin only  $\mu_{eff}$  value for Ir (IV) and Rh (IV) in octahedral coordination ( $1.73\mu_B$ ), with the differences being attributable to SOC through the  $g$ -factor. We see that  $\mu_{eff}$  decreases with increasing Rh concentration until the region  $0.5 < x < 0.8$  and then increases to  $2.03\mu_B$  for  $x = 1$  (Figure A.7(a)). The  $\theta$  values are 35.0 K and 57.7 K for  $\text{Li}_2\text{IrO}_3$  and  $\text{Li}_2\text{RhO}_3$  respectively which indicate antiferromagnetic interactions, consistent with a Curie-Weiss analysis for  $T > 100$  K. Thus, the Ir-Rh

solid solutions show systematic paramagnetic behavior and the AFM transition in  $\text{Li}_2\text{IrO}_3$  is suppressed quickly by Rh substitution over the entire measurement region.

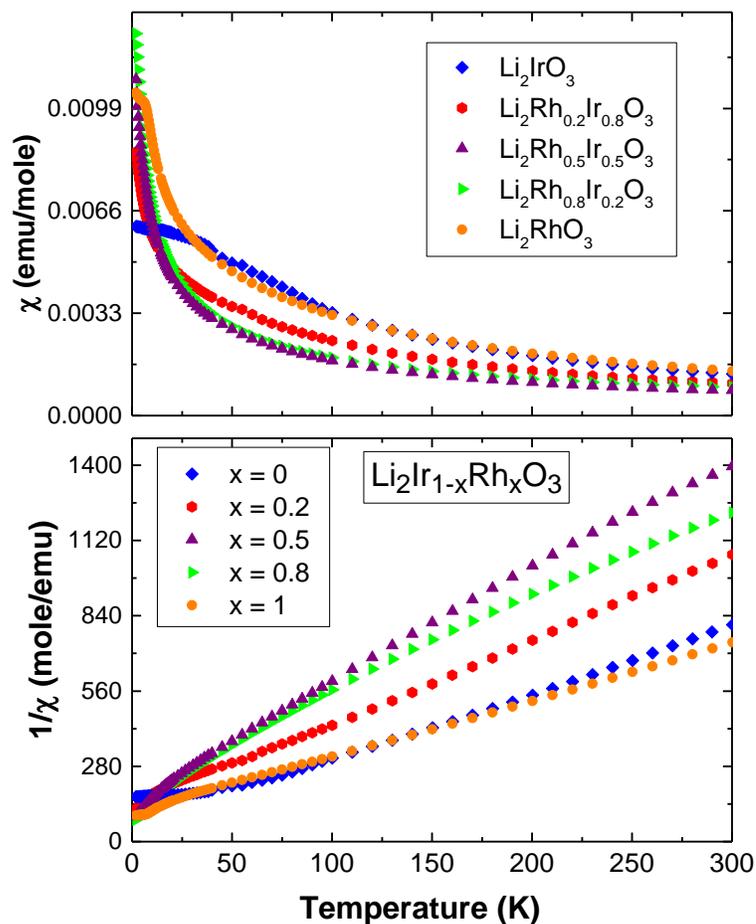

Figure A.6: Temperature dependence of magnetic susceptibility ( $\chi$ ) plot (top) and inverse magnetic susceptibility ( $1/\chi$ ) plot (bottom) for  $\text{Li}_2\text{Ir}_{1-x}\text{Rh}_x\text{O}_3$  ( $x = 0, 0.2, 0.5, 0.8$  and  $1.0$ ).

A reduced moment is difficult to explain if one assumes a random spatial config-

uration of only  $\text{Ir}^{4+}$  and  $\text{Rh}^{4+}$  ions, since i) the local environment does not change over the series, and ii) the spin-spin interaction, as derived from the Weiss constants is too small to cause an effective moment reduction above 100 K. As noted in Rh-dilution studies of the square lattice system  $\text{Sr}_2\text{IrO}_4$ , however [28,29], Ir can be readily stabilized in the pentavalent configuration ( $\text{Ir}^{5+}$ ) and Rh in the trivalent configuration ( $\text{Rh}^{3+}$ ), both of which are non-magnetic. Thus it is possible for the  $\text{Li}_2\text{Ir}_{1-x}\text{Rh}_x\text{O}_3$  solid solution members to have a lower effective moment and still maintain ionic charge balance if a fraction of  $\text{Ir}^{4+}$  ions transfers an electron to a neighboring  $\text{Rh}^{4+}$  ion, resulting in a  $\text{Ir}^{5+}/\text{Rh}^{3+}$  pair. The driving force for such a charge transfer (CT) mechanism might be the different on-site Coulomb repulsion energy  $U$ , which is 3–4 eV for 4d metals, about twice that found for 5d metals [20]. Since the honeycomb lattice is bipartite, full magnetic compensation at  $x = 0.5$  is possible if the site occupancy is perfectly ordered. Away from  $x = 0.5$ , and for maximum magnetic compensation, a lower limit for the effective moment is  $\mu_{eff} = \sqrt{1 - 2y\mu_m}$ , where  $y$  is the fraction of the total that are minority spins ( $y = x$  or  $(1-x)$  for  $x <$  or  $> 0.5$  respectively and  $\mu_m$  is the effective moment of the majority ion. For  $x < 0.5$ ,  $\mu_m = \mu_{eff}(\text{Ir}^{4+}) = 1.86 \mu_B$  and for  $x > 0.5$ ,  $\mu_m = \mu_{eff}(\text{Rh}^{4+}) = 2.03 \mu_B$ . This lower limit is plotted in Figure A.7(a). Clearly, the observed  $\mu_{eff}$  show only partial compensation, indicating that randomness is important for determining the number of uncompensated magnetic ions. In order to estimate  $\mu_{eff}(x)$  we construct a simple model in which the sites of a  $13 \times 13$  honeycomb lattice are randomly occupied by  $(1-x)$   $\text{Ir}^{4+}$  and  $x$   $\text{Rh}^{4+}$  ions. We then step through the lattice and identify  $\text{Ir}^{4+}/\text{Rh}^{4+}$  nearest neighbor pairs, which are

assumed to undergo CT and become non-magnetic. If more than one pair can be formed, we randomly select one of them. The value of  $\mu_{eff}$  is obtained by first counting the resulting unpaired atoms and assigning them the appropriate moment, either  $\text{Ir}^{4+}$  or  $\text{Rh}^{4+}$ . The effective moment in this “unscreened” model is then given by  $\mu_{us}=[z_{\text{Ir}}\mu_{\text{Ir}^{4+}}^2+z_{\text{Rh}}\mu_{\text{Rh}^{4+}}^2]^{1/2}$ , where  $z_{\text{Ir}}$  and  $z_{\text{Rh}}$  is the fraction of free Ir and Rh moments respectively. Simulations are performed for different starting configurations, and different ratios of Ir and Rh, and the uncertainty in  $\mu_{eff}$  derived from the resulting spread of  $\mu_{us}$  values. As shown in Figure A.7,  $\mu_{us}$  obtained by this method is greater than the maximum pairing assumption at all  $x$ , as expected. In addition,  $\mu_{us}$  is approximately symmetric about  $x = 0.5$ , with the small asymmetry arising from the slightly different  $\mu_{eff}$  values for  $\text{Ir}^{4+}$  and  $\text{Rh}^{4+}$ . A much larger asymmetry is displayed by the observed  $\mu_{eff}$  values, discussed next.

As seen in Figure A.7(a), the measured  $\mu_{eff}$  is larger than  $\mu_{us}$  for  $x < 0.5$ , and smaller than  $\mu_{us}$  for  $x > 0.5$ . Thus, in the Ir-rich phase the CT mechanism leading to  $\text{Ir}^{4+}/\text{Rh}^{3+}$  pairs seems to be screened, fewer CT pairs thus formed, and the density of residual magnetic moments is larger than expected in the unscreened scenario.

The source of such screening is not obvious, but may lie in the spin-orbit splitting of the  $\text{Ir}^{4+}$  six-fold  $t_{2g}$  multiplet, which is larger than in Rh, thus providing a barrier for charge transfer. As  $x$  increases towards 0.5,  $\mu_{eff}$  approaches  $\mu_{us}$ . As mentioned above, however, the number of stacking faults becomes substantial for  $x > 0.5$ . It is also likely that concurrently, the density of anti-site defects, in which Rh ions exchange places with Li, also becomes substantial. While the

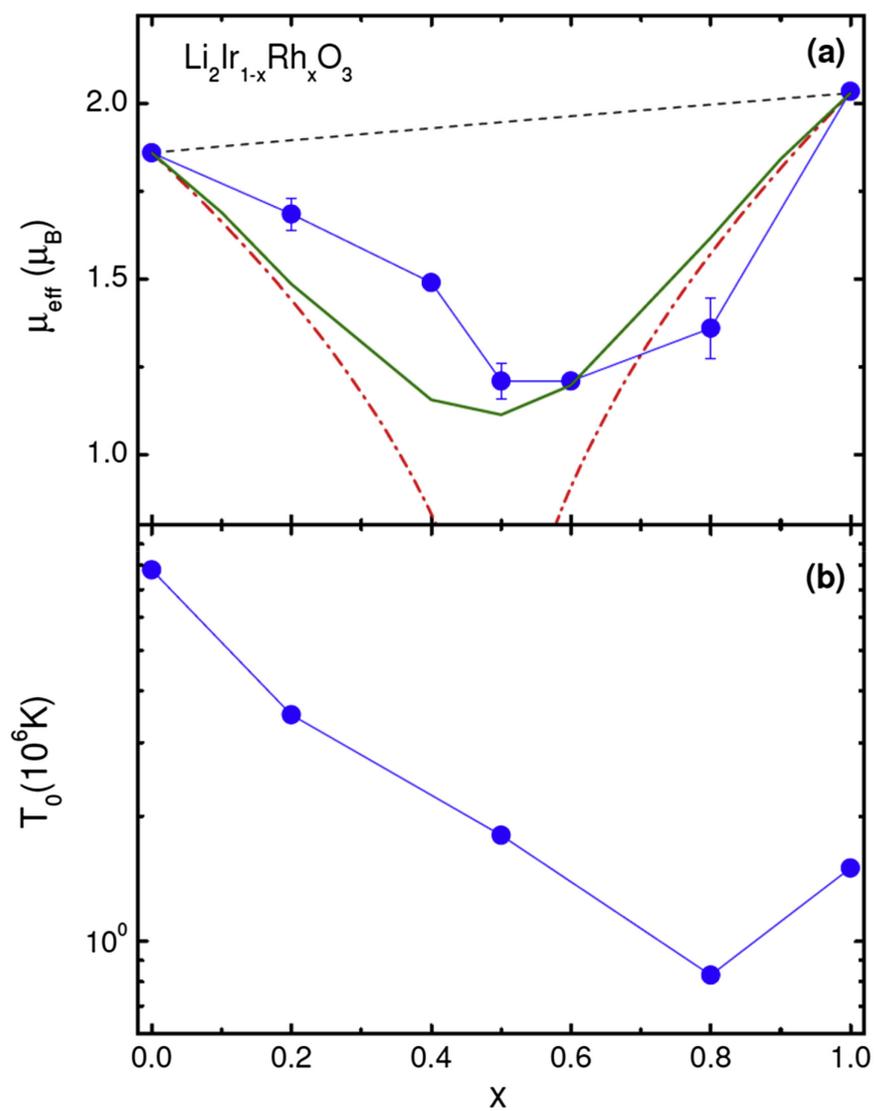

Figure A.7: (a) Variation of effective moment,  $\mu_{eff}$ , with  $x$  in  $\text{Li}_2\text{Ir}_{1-x}\text{Rh}_x\text{O}_3$  (solid blue circles). Models of  $\mu_{eff}$  variation discussed in the text are simple interpolation (dashed black line), charge-transfer between  $\text{Ir}^{4+}/\text{Rh}^{4+}$  pairs in an ordered lattice (dashed-dot red line) and unscreened random charge-transfer,  $\mu_{us}$  (solid green line). (b) The variation of the characteristic temperature,  $T_0$ , in a 2D variable range hopping model with  $x$ . Lines are drawn to guide the eye.

Li environment is octahedral, similar to the Ir or Rh environment, and as such the moment would be preserved, such an effect would work in opposition to the CT mechanism since it would reduce the number of nearest neighbor Ir<sup>4+</sup>/Rh<sup>4+</sup> pairs. For  $x > 0.5$ ,  $\mu_{eff}$  is smaller than  $\mu_{us}$ , which cannot be explained solely with local moments. We know, however, that  $\mu_{eff}$  of Li<sub>2</sub>RhO<sub>3</sub> is well-explained by local moments, which has been interpreted to result from the combination of quasi-molecular orbitals and large onsite  $U$ , as discussed by Mazin et al. [20]. A possible explanation for the reduction in  $\mu_{eff}$  for  $x > 0.5$  might lie in an enhanced charge mobility since delocalization correlates with reduced local moment. Such an “over-screened” CT process is reflected in resistivity,  $\rho(T)$ , which is reduced for  $0.5 < x < 1.0$ , as discussed next.

Low temperature  $\rho(T)$ , data for the compounds  $x = 0, 0.2, 0.5, 0.8$  and  $1.0$  are shown in Figure A.8(a). The room temperature values for the two end members are in reasonable agreement with previous experimental results [17,19,21] and  $\rho(T)$ , is semiconductor-like over the entire range of measurement. The  $\rho(T)$ , data for Li<sub>2</sub>RhO<sub>3</sub> is consistent with results of Luo et al. but is, not surprisingly, an order of magnitude greater than the high-frequency ( $>1$  MHz) results of Todorova et al. [19,21]. Previous transport studies on related honeycomb systems explained  $\rho(T)$ , in terms of 3D variable range hopping (VRH) for Na<sub>2</sub>IrO<sub>3</sub> [1] and Li<sub>2</sub>RhO<sub>3</sub> [21], and 2D VRH for the Li<sub>2</sub>Ir<sub>1-x</sub>Ru<sub>x</sub>O<sub>3</sub> [17]. We analyzed our data using the general formula for VRH ( $\rho = \rho_0 \exp[(T_0/T)^{1/(d+1)}]$ ) where  $d$  is the dimensionality, and  $\rho_0$  and  $T_0$  are fitting parameters. We found that the reduced  $\chi^2$  of the fits for all compounds except  $x = 0.8$  were minimized at  $d = 2$ , supporting the notion of

transport mainly within the honeycomb lattice.

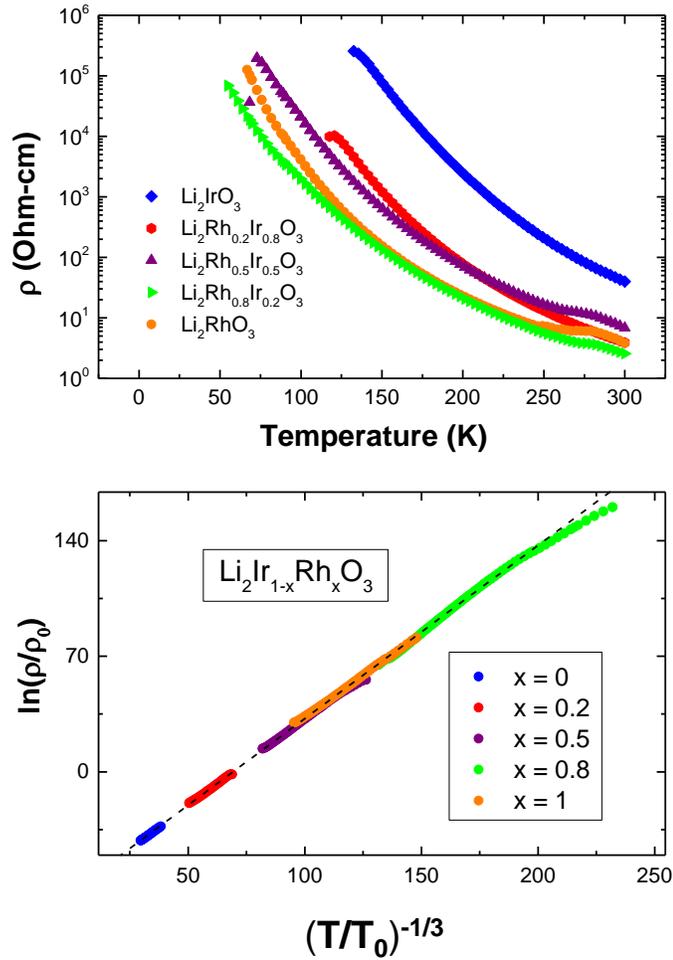

Figure A.8: Temperature-dependent, low-temperature resistivity plot (top) and 2D VRH plot for  $\text{Li}_2\text{Ir}_{1-x}\text{Rh}_x\text{O}_3$  ( $x = 0, 0.2, 0.5, 0.8$  and  $1.0$ ) (bottom).

The  $T_0$  and  $\rho_0$ , values obtained from these fits for each sample are listed in Table A.1. In Figure A.8(b) we show the resistivity data for all samples collapsed onto a  $d = 2$  VRH model. While the agreement is generally very good, the  $x =$

0.8 compound deviates significantly from VRH behavior in a manner that suggests a temperature-independent conduction channel in parallel with the 2D channel. Given the large number of stacking faults on the Rh-rich side of the series, it is possible that the related anti-site disorder [30] along with the lower  $U$  of Ir combine to create such a channel. High temperature resistivity and Seebeck coefficients for  $x = 0, 0.2, 0.5, 0.8$  and  $1.0$  are shown in Figure A.9. All samples are observed to be  $p$ -type semiconductors. However a transition from  $n$ -type to  $p$ -type is expected for  $\text{Li}_2\text{RhO}_3$  as observed by the negative  $S$  for it at room temperature suggesting carriers of both signs which is temperature dependent [31]. We note the large value of  $S$  found for  $x = 1$ , which suggests that the on-site Coulomb energy, suspected as a contributor to the small moments in the intermediate- $x$  range, is playing a substantial role in charge transport.

Table A.1: The fitting parameters  $T_0$  and  $\rho_0$  for  $\text{Li}_2\text{Ir}_{1-x}\text{Rh}_x\text{O}_3$  ( $x = 0, 0.2, 0.5, 0.8$  and  $1.0$ ).

Composition	$T_0(\text{K})$	$\rho_0$ (Ohm-cm)
$x = 0$	$7.80 \times 10^7$	$3.75 \times 10^{-11}$
$x = 0.2$	$3.51 \times 10^7$	$1.79 \times 10^{-9}$
$x = 0.5$	$1.84 \times 10^7$	$1.23 \times 10^{-7}$
$x = 0.8$	$9.16 \times 10^5$	$5.35 \times 10^{-7}$
$x = 1.0$	$1.50 \times 10^7$	$7.31 \times 10^{-8}$

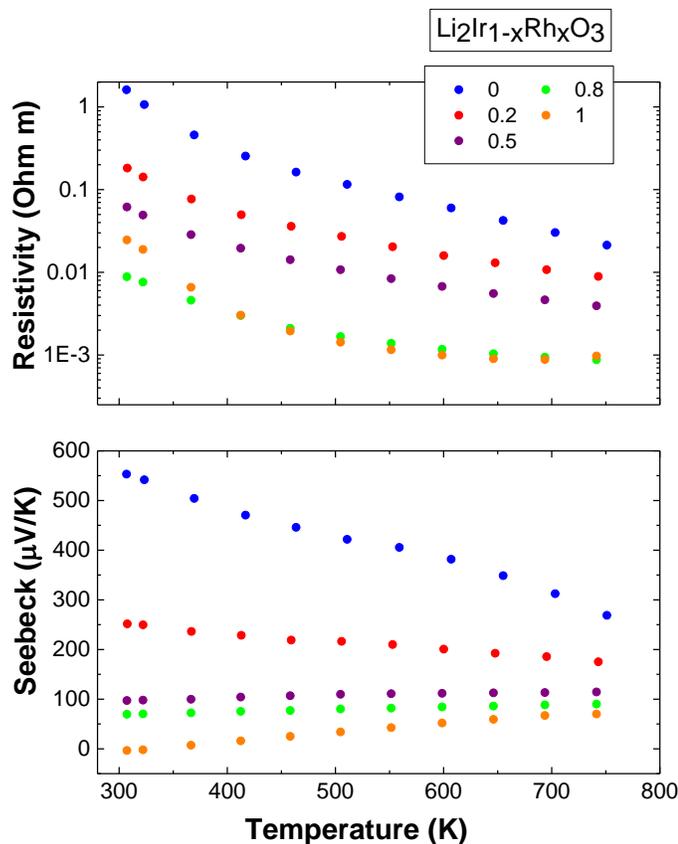

Figure A.9: (a) Temperature dependent, high temperature resistivity and (b) Seebeck coefficient plot for  $\text{Li}_2\text{Ir}_{1-x}\text{Rh}_x\text{O}_3$  ( $x = 0, 0.2, 0.5, 0.8$  and  $1.0$ ).

## A.5 Summary

We have synthesized the solid solution series  $\text{Li}_2\text{Ir}_{1-x}\text{Rh}_x\text{O}_3$  and studied it using magnetic and transport probes. We find a marked reduction of the effective moment over the entire range of dilution. This moment reduction is understood to arise from several factors: a charge transfer process between  $\text{Ir}^{4+}/\text{Rh}^{4+}$  pairs leading to nonmagnetic  $\text{Ir}^{5+}/\text{Rh}^{3+}$  pairs; large spin orbit splitting of the  $t_{2g}$  multiplet

on the Ir-rich side of the series; and large onsite  $U$  on the Rh-rich side of the series. Anti-site mixing may play a role in reducing the number of charge transfer processes. Apart from the complication introduced by anti-site mixing, the present study illuminates some of the issues associated with controlling the valence state in heavy d-element compounds. First, related to the high oxidation states of these  $j = 1/2$  species, stable neighboring oxidation states are often found, and can be induced by the doping process itself. Second, the tendency towards itineracy is balanced not only by the onsite  $U$ , but also by SOC. Finally, the combined effects of small- $U$  Ir and large- $U$  Rh can have dramatic consequences for transport in these systems.

## A.6 TOF Neutron Diffraction Refinements (not in manuscript)

Time of Flight (TOF) neutron diffraction measurements for  $\text{Li}_{2-x}\text{Ir}_{1-x}\text{Rh}_x\text{O}_3$  samples were collected at Oak Ridge National Laboratory POWGEN BL-11A SNS beamline. Rietveld refinement of  $\text{Li}_2\text{Ir}_{0.2}\text{Rh}_{0.8}\text{O}_3$  nominal composition sample is shown in Figure A.10. A pseudo-Voigt peak shape profile was chosen and parameters refined to obtain the best fit to the collected data. The space group was refined to be  $C2/m$ , with lattice dimensions  $a = 5.135 \text{ \AA}$ ,  $b = 8.871 \text{ \AA}$ ,  $c = 5.112 \text{ \AA}$ , and  $\beta = 109.92^\circ$ . Rietveld refinement shows a  $wR_p = 3.19\%$ . The atomic coordinates, occupancies, and isotropic displacement parameters are represented in Table A.2. For  $C2/m$  there are two unique atomic positions to describe describe the Li and Ir/Rh sites within the  $\text{Li}(\text{Ir}/\text{Rh})_2$  layer. Shown in Table A.2,

corresponding sites are labeled as  $4g$  and  $2a$  wyckoff sites. If no Li-M site disorder existed within the  $\text{LiM}_2$  layer, only Ir/Rh( $4g$ ) and Li( $2a$ ) would exist, with the Ir/Rh( $4g$ ) site describing the honeycomb ring. As shown from Table A.2 occupancies, a small percentage ( $\approx 13\%$ ) of Li-M site disorder exists within the  $\text{Li}(\text{Ir/Rh})_2$  layer. As shown by the  $2d$  and  $4h$  refined occupancies, no Ir/Rh was detected within the Li-layers. The stoichiometry derived from occupancy refinements is  $\text{Li}_2\text{Ir}_{0.203}\text{Rh}_{0.797}\text{O}_3$ .

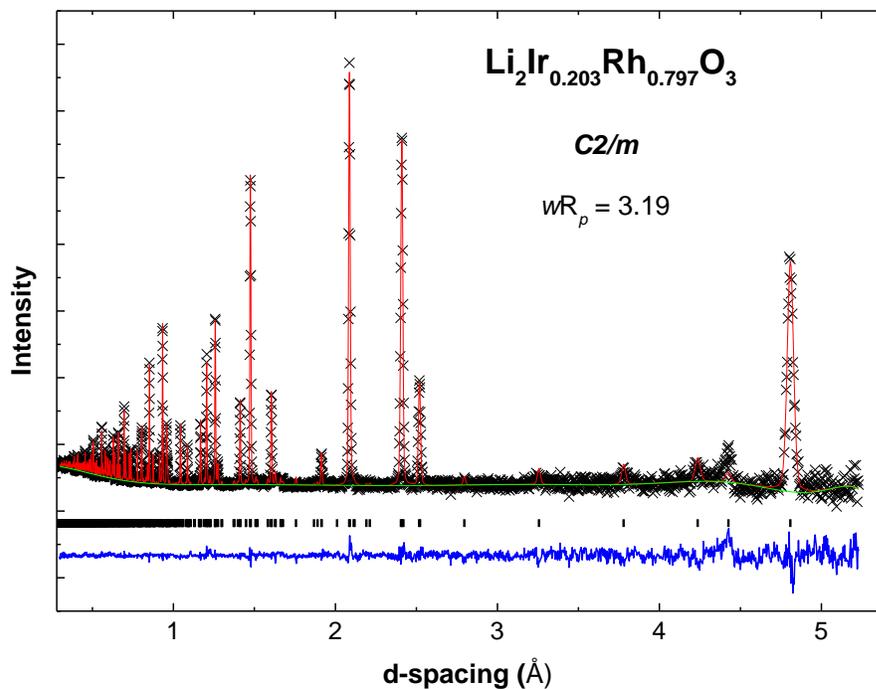

Figure A.10: TOF Neutron refinement of nominal composition  $\text{Li}_2\text{Ir}_{0.2}\text{Rh}_{0.8}\text{O}_3$ . Observed (black crosses) and calculated (solid red line) profiles, background (green), and difference curve ( $I_{obs} - I_{calc}$ ) (blue) are shown for each refinement. The vertical bars indicate the expected reflection positions with black representing  $\text{Li}_2\text{Ir}_{0.2}\text{Rh}_{0.8}\text{O}_3$  *C2/m*. Resulting stoichiometric identities and  $wR_p$  are represented.

## Appendix D: Programs

Programs to mitigate certain tasks have been sought after in the Functional Materials Research Group. Four programs were written in Python and converted to windows executable programs (author: Max Wallace). The "MAS TOOLBAR" was created to host the four programs (Figure D.1) (author: Max Wallace).

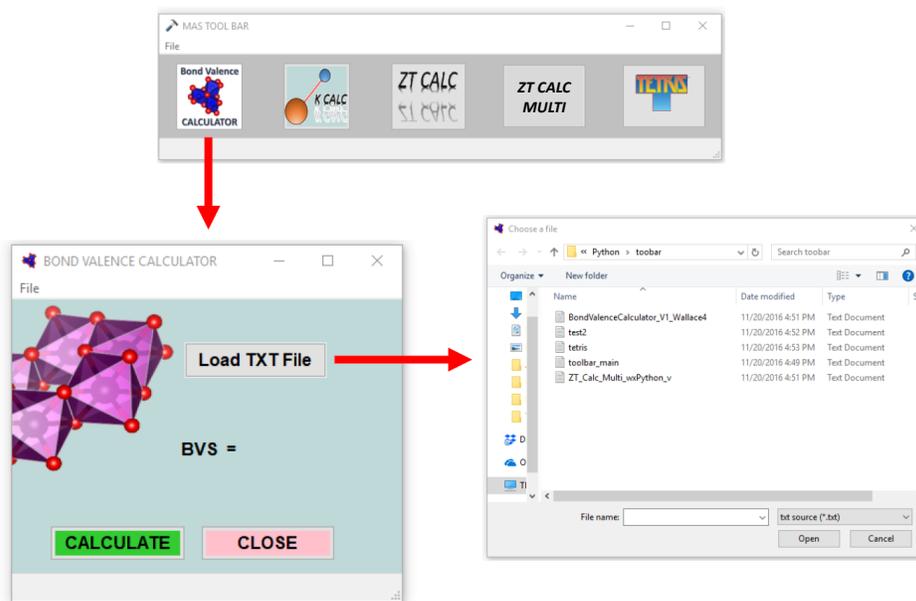

Figure D.1: The "MAS TOOLBAR" with the following programs: Bond Valence Calculator, K-Calc, ZT Calc, ZT Calc MULTI, and Tetris.

A brief definition of each of the four programs is provided in Table D.1. Python code for "ZT Calc MULTI" and "K-Calc" are provided below.

Table D.1: Brief description of programs written by Max Wallace

<p><b>Bond Valence Calculator:</b> Used to calculate the bond valence sum (BVS) around each metal atom in a compound. The BVS can be compared to the expected oxidation state of that atom. The bond valence is used to validate newly determined crystal structures.</p>
<p><b>K-Calc:</b> Calculates the dielectric constant of a compound using the Clausius-Mossotti relation. The Clausius-Mossotti relation connects polarizability to dielectric permittivity.</p>
<p><b>ZT Calc:</b> Calculates the Figure of Merit (ZT) of a thermoelectric material. The electrical conductivity, Seebeck value, and total thermal conductivity values must be known.</p>
<p><b>ZT Calc MULTI:</b> compiles the raw data collected from the laser flash instrument (thermal diffusion) and ZEM instrument (electrical conductivity and Seebeck) into a single excel spreadsheet with raw data, corrected data and calculated ZT for each temperature for a given sample.</p>
