[1] We propose the Breathing Earth System Simulator (BESS), an upscaling approach to quantify global gross primary productivity and evapotranspiration using MODIS with a spatial resolution of 1–5 km and a temporal resolution of 8 days. This effort is novel because it is the first system that harmonizes and utilizes MODIS Atmosphere and Land products on the same projection and spatial resolution over the global land. This enabled us to use the MODIS Atmosphere products to calculate atmospheric radiative transfer for visible and near infrared radiation wave bands. Then we coupled atmospheric and canopy radiative transfer processes, with models that computed leaf photosynthesis, stomatal conductance and transpiration on the sunlit and shaded portions of the vegetation and soil. At the annual time step, the mass and energy fluxes derived from BESS showed strong linear relations with measurements of solar irradiance ($r^2 = 0.95$, relative bias: 8%), gross primary productivity ($r^2 = 0.86$, relative bias: 5%) and evapotranspiration ($r^2 = 0.86$, relative bias: 15%) in data from 33 flux towers that cover seven plant functional types across arctic to tropical climatic zones. A sensitivity analysis revealed that the gross primary productivity and evapotranspiration computed in BESS were most sensitive to leaf area index and solar irradiance, respectively. We quantified the mean global terrestrial estimates of gross primary productivity and evapotranspiration between 2001 and 2003 as $118 \pm 26 \text{ PgC yr}^{-1}$ and $500 \pm 104 \text{ mm yr}^{-1}$ (equivalent to $63,000 \pm 13,100 \text{ km}^3 \text{ yr}^{-1}$), respectively. BESS-derived gross primary productivity and evapotranspiration estimates were consistent with the estimates from independent machine-learning, data-driven products, but the process-oriented structure has the advantage of diagnosing sensitivity of mechanisms. The process-based BESS is able to offer gridded biophysical variables everywhere from local to the total global land scales with an 8-day interval over multiple years.

1. Introduction

[2] There is great interest and need to estimate terrestrial trace gas and energy fluxes (e.g., CO₂ and water) everywhere (e.g., local to the global land) and all the time (e.g.,

8-daily over multiple years). There have been recent advances to produce such estimates by using machine-learning techniques in conjunction with remote sensing data and the flux tower data derived from sparse networks [Beer *et al.*, 2010; Jung *et al.*, 2010; Xiao *et al.*, 2010]. However, the

machine-learning technique relies on empirical relationships between forcing variables and fluxes [Jung *et al.*, 2009], and it only works within the domain of data on which it is trained.

[3] A process-based diagnostic model that is calibration-free and can be applied globally has the advantage of explaining the response of ecosystem metabolism to global change. This task requires understanding and quantifying a set of coupled and highly nonlinear biophysical processes that span 14 orders of magnitude in time and space [Jarvis, 1995; Osmond *et al.*, 1980]. While a generation ago, such an approach was discouraged due to concerns about the issue of “garbage-in and garbage-out” [de Wit, 1970]. Today, advancements in remote sensing, micrometeorology and ecophysiology together with some recent meta-analysis studies enable us to deduce key parameters and generate input variables to quantify mass and energy fluxes at high spatial and temporal resolution and across vast spatial and temporal scales.

[4] The key processes that are essential to quantify trace gas and energy fluxes have been identified. First, photosynthesis and transpiration needs to be coupled as they constrain each other via the stomata [Baldocchi, 1997; Baldocchi and Meyers, 1998; Collatz *et al.*, 1991; Leuning *et al.*, 1995]. Second, a two-leaf model (i.e., sunlit and shaded leaves) is more effective than a big leaf model; it is needed to consider nonlinear processes in canopy radiative transfer and trace gas fluxes [Chen *et al.*, 1999; Dai *et al.*, 2004; de Pury and Farquhar, 1997; Norman, 1982; Sinclair *et al.*, 1976; Wang and Leuning, 1998]. Third, foliar clumping effects should be considered as they influence canopy radiative transfer [Norman and Jarvis, 1975; Ryu *et al.*, 2010a, 2010b], change the proportion of sunlit and shade leaves, and consequently modify canopy fluxes [Baldocchi and Wilson, 2001; Baldocchi *et al.*, 1984; Chen *et al.*, 1999; Lemeur and Blad, 1974]. Fourth, atmospheric and land processes should be coupled as the environment of incoming short-wave radiation (e.g., the amount of diffuse radiation, solar zenith angle) substantially modulates surface reflectance and canopy processes [Alton *et al.*, 2007; Gu *et al.*, 2002; Kobayashi and Iwabuchi, 2008; Ryu *et al.*, 2010c].

[5] Most land surface flux models that use satellite-derived parameters and variables have not yet incorporated those processes. Typically, gross primary productivity (GPP) has been estimated using light use efficiency models [Hilker *et al.*, 2009; Ruimy *et al.*, 1996; Running *et al.*, 2004] or vegetation indices [Huete *et al.*, 2008; Sims *et al.*, 2008]. Evapotranspiration (ET) has been inferred from the energy balance residual [Norman *et al.*, 1995; Su, 2002], the Priestley-Taylor equation [Fisher *et al.*, 2008; Priestley and Taylor, 1972], the Penman-Monteith equation [Cleugh *et al.*, 2007; Monteith, 1965; Mu *et al.*, 2007] or the hydrological balance [Rodell *et al.*, 2004]. More recently, a statistical approach using machine-learning techniques has emerged as a new tool to quantify GPP and ET [Beer *et al.*, 2010; Jung *et al.*, 2009; Xiao *et al.*, 2010]. However, even fewer studies have attempted to connect GPP and ET in concert, at global scales [Yuan *et al.*, 2010]. Furthermore, many global models used data inputs and parameters from a mixture of fine (1 km) and coarse (0.5 to 1 degree) space scales. For example land surface properties like leaf area index (LAI), vegetation indices, and land surface temperature were

derived with ~ 1 km resolution. In contrast, many models derived incoming solar irradiance, the most important driver of biophysical processes, and meteorological variables from coarse reanalysis data such as 1-degree resolution of DAO [Zhao *et al.*, 2005] and ISLSCP-II [Fisher *et al.*, 2008], 0.5-degree resolution of MERRA [Yuan *et al.*, 2010], and 0.125-degree resolution of NLDAS [McCabe *et al.*, 2008]. Thus it is important to recognize that there is a scale mismatch between land surface and atmospheric inputs that remains a challenge.

[6] Recent advances in remote sensing, ecophysiology and recent meta-analysis offer new opportunities to incorporate the key processes mentioned above into remote-sensing-based land surface models. The tight correlation between albedo and nitrogen concentration at closed canopy in temperate and boreal forests [Hollinger *et al.*, 2010; Ollinger *et al.*, 2008] enables us to apply Farquhar’s photosynthesis model at coarse spatial scales using remote sensing. Several studies have demonstrated that MODIS atmospheric products can provide solar irradiance and meteorological variables at high spatial resolution (1–5 km) [Liang *et al.*, 2006; Ryu *et al.*, 2008a; Van Laake and Sanchez-Azofeifa, 2004], which provides a possibility to couple land surface and atmospheric processes at high spatial resolution. Next, a global scale foliar clumping index map by using multiangle satellite images has been developed and tested [Chen *et al.*, 2005; Pisek *et al.*, 2010]. Thus accurate calculation of canopy radiative transfer that is important in controlling GPP and ET has become possible by integrating incoming solar irradiance, LAI and clumping index information.

[7] In spite of the recent advances mentioned above, one important barrier to global scale remote sensing research remains. That is the computational resource and data storage. Global scale remote sensing study requires handling terabytes of data, in particular when targeting high spatial resolution (e.g., 1–5 km). Many environmental scientists do not have access to a high-performance computing to overcome such computational barriers. Recently, as an alternative, the cloud computing service (e.g., Microsoft Azure, Amazon EC2), a kind of web-based super computer, was used to perform these intensive time-demanding computations [Li *et al.*, 2010]. Also, corporate collaborations with scientists have opened doors for global analysis. For example, a significant advance is that Landsat satellite imagery from the last 25 years (much of which was not previously available online) made available by U.S. Geological Survey has been processed by the Google Earth Engine using an analytical tool [Asner *et al.*, 2005], which will allow fine-scale mapping of deforestation and forest degradation globally (<http://earthengine.googlelabs.com>).

[8] In this study, we present the Breathing Earth System Simulator (BESS) built on the Microsoft Azure cloud computing service. BESS couples algorithms and models that compute atmospheric radiative transfer, photosynthesis, and leaf and soil energy balances by integrating a range of data streams in MODIS atmospheric and land products with ancillary data. Together, this system can produce computations of canopy evaporation and photosynthesis from 1- to 5-km resolution across the globe at an 8-day time interval.

[9] The goals of this paper are: first, we describe the BESS algorithms. Then we evaluate the computational products of

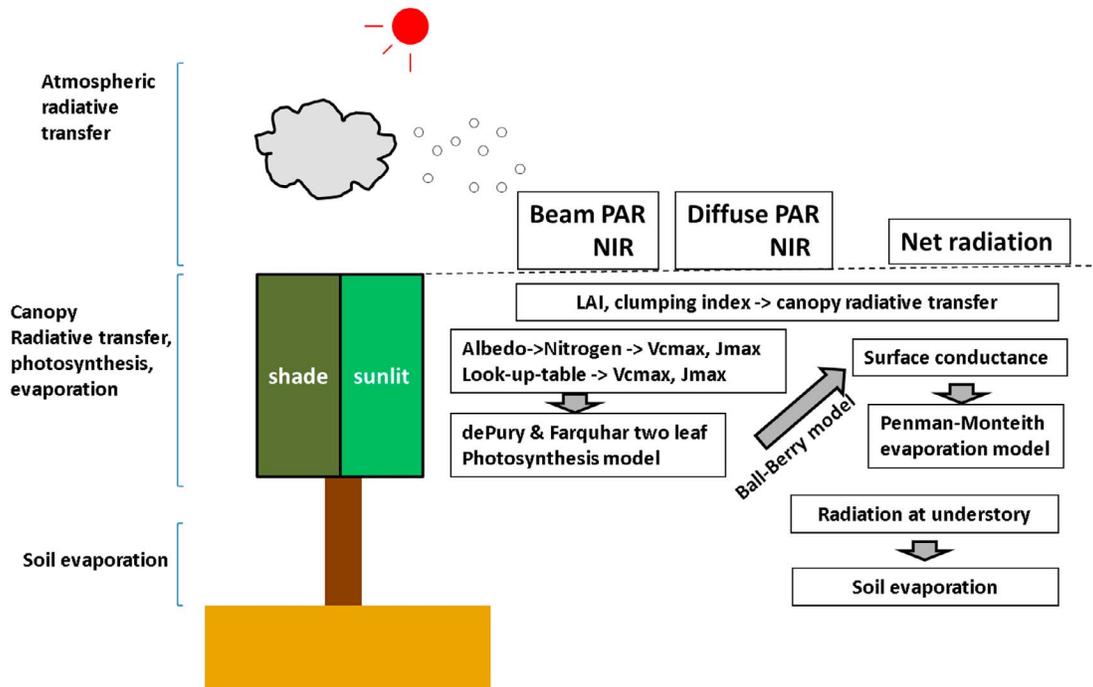

Figure 1. Overview of the coupled biophysical model (BESS).

BESS against 1) data from 33 flux towers across 7 plant functional types spanning arctic to tropical climatic zones, 2) data-driven GPP and ET products, and 3) basin scale water balance data. Last, we use BESS system to address several key scientific questions that include: 1) can BESS that does not explicitly consider soil water balance estimate GPP and ET reliably? 2) what are the global terrestrial estimates of GPP and ET at annual time scales? 3) how sensitive is BESS model to environmental and biological drivers?

2. Methods

2.1. BESS Description

[10] BESS is a biophysical model (Figure 1). In this section, we describe coupled the key modules that include: atmospheric radiative transfer (section 2.1.1), canopy radiative transfer (section 2.1.2), canopy photosynthesis (section 2.1.3), maximum carboxylation rate (section 2.1.4), two-leaf canopy conductance and temperature (section 2.1.5), and evapotranspiration (section 2.1.6), which are important to drive this process based approach.

2.1.1. Atmospheric Radiative Transfer Model

[11] To calculate incoming shortwave radiation ($R_{s,i}$, see nomenclature in Appendix A), photosynthetic active radiation ($R_{p,i}$) and near-infrared radiation ($R_{n,i}$) for the beam and diffuse components at the top of canopy, we used an atmospheric radiative transfer model (FLiES) based on the Monte-Carlo approach [Iwabuchi, 2006; Kobayashi and Iwabuchi, 2008]. This model was compared with two other atmospheric radiative transfer models, 6S model [Vermeulen *et al.*, 1997] and Streamer V3.0 [Key and Schweiger, 1998], and they showed good agreement among each other. The relative RMSE was 4.3% and 6.7%, for between the current model and 6S model, and for between the current model and

Streamer V3.0, respectively across a range of atmospheric condition [Kobayashi and Iwabuchi, 2008]. To apply the atmospheric radiative transfer model to the globe and reduce computational needs, we developed a look-up-table for each radiation component. The input variables include: 1) solar zenith angle (5, 10, ..., 85°), 2) aerosol optical thickness at 550 nm (0.1, 0.3, 0.5, 0.7, 0.9), 3) cloud optical thickness (0.1, 0.5, 1, 5, 10, 20, 40, 60, 80, 110), land surface albedo (0.1, 0.4, 0.7), 4) cloud top height (1000, 3000, 5000, 7000, 9000 m), 5) atmospheric profile type (tropical zone for Tropical type, arid and temperate zones for Midlatitude type, snow and ice zones for High-latitude type; the climate zones were defined by Köppen-Geiger global climate classification map (see section 2.4.4), the atmospheric profile was characterized by Hess *et al.* [1998]), 6) aerosol type (continental average except for tropical climatic zone whose aerosol type was assigned as urban to consider high aerosol loading in tropics [Martin *et al.*, 2010], the aerosol type was characterized by Hess *et al.* [1998]), and 7) cloud type (cloud-free, stratus continental, cumulus continental) [Hess *et al.*, 1998]. We prepared the input data from a range of MODIS data streams including MOD04 (aerosol optical thickness), MOD06 (solar zenith angle, cloud optical thickness, cloud top height), and MCD43 (albedo). As MODIS did not provide the types of aerosol and cloud, we used two categories for aerosol (continental average and urban), and applied two categories for cloud type (stratus continental and cumulus continental). We used the cumulus continental type for the tropical climate zone (see section 2.4.4), and the stratus continental type for the other areas. The sensitivity analysis revealed that different cloud and aerosol type combinations could lead to a maximum difference of 10% and 15%, respectively in the incoming Q_p calculation (data not shown).

2.1.2. Two-Leaf Canopy Radiative Transfer Model

[12] We applied a simple canopy radiative transfer model that quantified absorbed photosynthetically active radiation (PAR), near-infrared radiation (NIR) and longwave radiation for sunlit and shade leaves. The sunfleck penetration (f_{sun}), the probability of leaf area being irradiated by the direct beam, plays a key role in the model. The sunlit and shaded leaves receive different amounts of radiation thus the expected value of canopy fluxes should be weighted by the fractions of sunlit and shade leaves to consider nonlinear processes in the canopy fluxes. *Gutschick* [1991] derived f_{sun} at canopy depth L for clumped canopy:

$$f_{sun}(L) = \frac{\exp(-kL\Omega) - \exp(-k(L+dL)\Omega)}{kL} = \Omega \exp(-kL\Omega) \quad (1)$$

All symbols are defined in Appendix A. The list of optical parameters appears in Table S1 in the auxiliary material.¹ Note that Ω was multiplied before the exponential term too ($\Omega \exp(-kL\Omega)$). For a canopy with a random leaf spatial distribution, $\Omega = 1$ and equation (1) becomes the conventional gap fraction equation ($= \exp(-kL)$).

2.1.2.1. Absorbed Photosynthetically Active Radiation by Sunlit and Shade Leaves

[13] We modified the PAR penetration model [*de Pury and Farquhar*, 1997], by incorporating foliar clumping effects and reflected PAR from the soil. We replaced $\exp(-kL)$ in the work by *de Pury and Farquhar* [1997] with equation (1), and re-derived the set of equations that depend upon this relation. Total absorbed incoming PAR by the canopy (Q_P) is

$$Q_{P\downarrow} = (1 - \rho_{cbP})I_{Pb}(0)[1 - \exp(-k'_{Pb}L_c\Omega)] + (1 - \rho_{cdP})I_{Pd}(0)[1 - \exp(-k'_{Pd}L_c\Omega)] \quad (2)$$

where 0 and L_c indicate the leaf area index at the top and the bottom of the canopy, respectively. ρ_{cbP} and ρ_{cdP} are canopy reflectance for beam PAR and diffuse PAR, respectively. I_{Pb} and I_{Pd} are direct beam PAR and diffuse PAR, respectively. k'_{Pb} and k'_{Pd} are extinction coefficient for beam and scattered beam PAR, and for diffuse and scattered diffuse PAR, respectively.

[14] The absorbed incoming beam PAR by sunlit leaves ($Q_{PbSun\downarrow}$) is

$$Q_{PbSun\downarrow} = I_{Pb}(0)(1 - \sigma_{PAR})[1 - \exp(-k_bL_c\Omega)] \quad (3)$$

where σ_{PAR} is leaf scattering coefficient for PAR. k_b is extinction coefficient for black leaves.

[15] The absorbed incoming diffuse PAR by sunlit leaves ($Q_{PdSun\downarrow}$) is

$$Q_{PdSun\downarrow} = I_{Pd}(0)(1 - \rho_{cdP})[1 - \exp(-(k'_{Pd} + k_b)L_c\Omega)]k'_{Pd} / (k'_{Pd} + k_b) \quad (4)$$

The absorbed incoming scattered PAR by sunlit leaves ($Q_{PsSun\downarrow}$) is

$$Q_{PsSun\downarrow} = I_{Pb}(0)[(1 - \rho_{cbP})(1 - \exp(-(k'_{Pb} + k_b)L_c\Omega))k'_{Pb} / (k'_{Pb} + k_b) - (1 - \sigma_{PAR})(1 - \exp(-2k_bL_c\Omega))/2] \quad (5)$$

The total absorbed incoming PAR by sunlit leaves is

$$Q_{PSun\downarrow} = Q_{PbSun\downarrow} + Q_{PdSun\downarrow} + Q_{PsSun\downarrow} \quad (6)$$

The total absorbed incoming PAR by shade leaves is

$$Q_{PSh\downarrow} = Q_{P\downarrow} - Q_{PSun\downarrow} \quad (7)$$

A proportion of the incoming PAR penetrates through the canopy to the soil surface and is reflected up into the canopy, which could be significant in open canopy with bright background. The PAR absorbed by the sunlit leaves as a result of that reflected by the soil is

$$Q_{PSun\uparrow} = [(1 - \rho_{cbP})I_{Pb}(0) + (1 - \rho_{cdP})I_{Pd}(0) - (Q_{PSun\downarrow} + Q_{PSh\downarrow})] \times \rho_{sP} \times \exp(-k'_{Pd}L_c\Omega) \quad (8)$$

where ρ_{sP} is soil reflectance for PAR.

[16] The PAR absorbed by the shade leaves as a result of that reflected by the soil is

$$Q_{PSh\uparrow} = [(1 - \rho_{cbP})I_{Pb}(0) + (1 - \rho_{cdP})I_{Pd}(0) - (Q_{PSun\downarrow} + Q_{PSh\downarrow})] \times \rho_{sP} \times [1 - \exp(-k'_{Pd}L_c\Omega)] \quad (9)$$

Finally, the total PAR absorbed by the sunlit and shade leaves is

$$Q_{PSun} = Q_{PSun\downarrow} + Q_{PSun\uparrow} \quad (10)$$

$$Q_{PSh} = Q_{PSh\downarrow} + Q_{PSh\uparrow} \quad (11)$$

2.1.2.2. Absorbed Near-Infrared Radiation by Sunlit and Shade Leaves

[17] The absorbed NIR by canopy has the same form as the absorbed PAR in the canopy. However, the canopy radiative transfer of NIR differs from PAR because photons are scattered more in the NIR region within the canopy. *Goudriaan* [1977] showed that the NIR penetration may follow the Beer's law after modifying the extinction coefficient for beam and scattered beam NIR (k'_{Nb}) and for diffuse and scattered diffuse NIR (k'_{Nd}):

$$k'_{Nb} = k_b \sqrt{1 - \sigma_{NIR}} \quad (12)$$

$$k'_{Nd} = 0.35 \sqrt{1 - \sigma_{NIR}} \quad (13)$$

where σ_{NIR} is leaf scattering coefficient for NIR.

[18] The total incoming NIR absorbed by sunlit leaves is

$$Q_{NSun\downarrow} = I_{Nb}(0)(1 - \sigma_{NIR})(1 - \exp(-k_bL_c\Omega)) + I_{Nd}(0)(1 - \rho_{cdN})(1 - \exp(-(k'_{Nd} + k_b)L_c\Omega))k'_{Nd} / (k'_{Nd} + k_b) + I_{Nb}(0)[(1 - \rho_{cbN})(1 - \exp(-(k'_{Nb} + k_b)L_c\Omega))k'_{Nb} / (k'_{Nb} + k_b) - (1 - \sigma_{NIR})(1 - \exp(-2k_bL_c\Omega))/2] \quad (14)$$

where ρ_{cbN} and ρ_{cdN} are canopy reflectance for beam NIR and diffuse NIR, respectively. I_{Nb} and I_{Nd} are direct beam NIR and diffuse NIR, respectively. k'_{Nb} and k'_{Nd} are extinction coefficient for beam and scattered beam NIR, and for diffuse

¹Auxiliary materials are available in the HTML. doi:10.1029/2011GB004053.

and scattered diffuse NIR, respectively. σ_{NIR} is leaf scattering coefficient for NIR.

[19] The total incoming NIR absorbed by shade leaves is

$$Q_{NSh\downarrow} = (1 - \rho_{cbN})I_{Nb}(0)(1 - \exp(-k'_{Nb}L_c\Omega)) + (1 - \rho_{cdN})I_{Nd}(0)(1 - \exp(-k'_{Nd}L_c\Omega)) - Q_{NSun\downarrow} \quad (15)$$

The NIR absorbed by sunlit leaves as a result of that reflected by the soil is

$$Q_{NSun\uparrow} = [(1 - \rho_{cbN})I_{Nb}(0) + (1 - \rho_{cdN})I_{Nd}(0) - (Q_{NSun\downarrow} + Q_{NSh\downarrow})] \times \rho_{sN} \times \exp(-k'_{Nd}L_c\Omega) \quad (16)$$

where ρ_{sN} is soil reflectance for NIR.

[20] The NIR absorbed by shade leaves as a result of that reflected by the soil is

$$Q_{NSh\uparrow} = [(1 - \rho_{cbN})I_{Nb}(0) + (1 - \rho_{cdN})I_{Nd}(0) - (Q_{NSun\downarrow} + Q_{NSh\downarrow})] \times \rho_{sN} \times [1 - \exp(-k'_{Nd}L_c\Omega)] \quad (17)$$

Finally, total NIR absorbed by sunlit and shade leaves is

$$Q_{NSun} = Q_{NSun\downarrow} + Q_{NSun\uparrow} \quad (18)$$

$$Q_{NSh} = Q_{NSh\downarrow} + Q_{NSh\uparrow} \quad (19)$$

2.1.2.3. Absorbed Longwave Radiation by Sunlit and Shade Leaves

[21] We calculated longwave radiation absorbed by sunlit (Q_{LSun}) and shade leaves (Q_{LSH}) using the *Wang and Leuning* [1998] model.

$$Q_{LSun} = -k'_L\sigma T_a^4(\epsilon_l(1 - \epsilon_a)(1 - \exp(-(k_b + k'_L)L_c))/(k_b + k'_L) + (1 - \epsilon_s)(\epsilon_l - \epsilon_a)(1 - \exp(-2k'_L L_c))/(2k'_L) \cdot (1 - \exp(-(k_b - k'_L)L_c))/(k_b - k'_L)) - c_p g_r(T_{Sun} - T_a) \quad (20)$$

where k'_L is extinction coefficient for longwave radiation. ϵ_a , ϵ_l and ϵ_s are emissivity for air, leaf and soil, respectively. c_p is specific heat of the air, g_r is radiative conductance. T_{Sun} and T_a are sunlit leaf and air temperature, respectively.

$$Q_{LSH} = -k'_L\sigma T_a^4(\epsilon_l(1 - \epsilon_a)(1 - \exp(-k'_L L_c))/k'_L - (1 - \epsilon_s) \cdot (\epsilon_l - \epsilon_a) \times \exp(-k'_L L_c)(1 - \exp(-k'_L L_c))/k'_L) - Q_{LSun} - c_p g_r(T_{Sun} - T_a) - c_p g_r(T_{Sh} - T_a) \quad (21)$$

where T_{Sh} is shade leaf temperature.

2.1.2.4. Net Radiation

[22] We calculated net radiation by extending the MODIS derived clear sky net radiation scheme [Ryu *et al.*, 2008a] into the whole sky condition that includes clear and cloudy conditions. The atmospheric radiative transfer model enabled us to calculate the incoming shortwave radiation under the whole sky condition. We briefly present the procedure used in the net radiation calculation here. The outgoing shortwave radiation was calculated as the product of incoming solar radiation and land surface albedo from MODIS (MCD43B3). For the cloudy days, we used the

white-sky albedo which represents the albedo for diffuse conditions. For the clear sky days, we calculated actual albedo by using a look-up-table provided by Boston University MODIS BRDF project (<http://www-modis.bu.edu/brdf/userguide/tools.html>). The look-up-table requires solar zenith angle, aerosol optical thickness, which all derived from the MOD04_L2 (aerosol product). For the incoming longwave radiation, we used the *Prata* [1996] model. Input data include air and dew point temperature at the screen level, which were derived from MOD07_L2 (atmospheric profile product). Under cloudy conditions when the MOD07_L2 does not provide temperature information, we used the NCEP/NCAR reanalysis derived temperature data included in MOD06_L2 only. The fraction of cloud cover per each pixel was extracted from MOD06_L2 (1 km), and the incoming longwave radiation for clear [*Prata*, 1996] and cloudy (σT_a^4) conditions were combined to produce the incoming longwave radiation per each pixel [*Crawford and Duchon*, 1999]. The outgoing longwave radiation was calculated using land surface emissivity and land surface temperature from MOD11_L2 (land surface temperature product). For the cloudy sky areas, we used the land surface temperature from the NCEP/NCAR reanalysis data.

2.1.3. Photosynthesis

[23] We used the biochemical photosynthesis models for C3 [*Collatz et al.*, 1991; *Farquhar et al.*, 1980] and C4 plants [*Collatz et al.*, 1992]. The information on the proportion of C3 and C4 plants per pixel is given in section 2.4.3. The two-leaf canopy photosynthesis was calculated using:

$$A_{c,j} = \min\{A_{l,j}, A_{v,j}, A_{s,j}\} - R_{c,j} \quad (22)$$

where $j = Sun$ or Sh indicate sunlit or shade leaf, respectively.

[24] A_l is the light limited rate of CO₂ assimilation (see symbols in Appendix A):

$$A_{l,j} = J_{\max,j} \frac{p_i - \Gamma_{*,j}}{4(p_i + 2\Gamma_{*,j})} \text{ for C3 species} \quad (23a)$$

$$A_{l,j} = 0.067 \times Q_{Pj} \text{ for C4 species} \quad (23b)$$

[25] A_v is the rubisco limited rate of CO₂ assimilation:

$$A_{v,j} = V_{\max,j} \left(\frac{p_i - \Gamma_{*,j}}{p_i + K_{c,j}(1 + O/K_{o,j})} \right) \text{ for C3 species} \quad (24a)$$

$$A_{v,j} = V_{\max,j} \text{ for C4 species} \quad (24b)$$

[26] A_s is the capacity for the export or utilization of the products of photosynthesis for C3 species, and CO₂ limited flux for C4 species:

$$A_{s,j} = 0.5V_{\max,j} \text{ for C3 species} \quad (25a)$$

$$A_{s,j} = 0.7 \times 10^6 \times \frac{P_i}{P} \text{ for C4 species} \quad (25b)$$

We fixed the ratio of leaf internal CO₂ concentration to the ambient CO₂ concentration as 0.7 (C3 species) and 0.4 (C4 species) [Baldocchi, 1994; Jones, 1992; Norman, 1982; Wong et al., 1979].

[27] R_c is the two-leaf canopy respiration.

$$R_{c,j} = V_{\max,j}^{25C} \times 0.015 \times \exp\{E_a - K_c(T_j - 298)/(298 \times R \times T_j)\}$$

for C3 species (26a)

$$R_{c,j} = V_{\max,j}^{25C} \times 0.025 \times 2^{\{(T_j - 298)/10 / (1 + \exp(1.3 \times (T_j - 328)))\}}$$

for C4 species (26b)

2.1.4. Maximum Carboxylation Rate (V_{\max})

[28] The V_{\max} is a key parameter in the Farquhar photosynthesis model [Farquhar et al., 1980; Houborg et al., 2009; Wang et al., 2007]. Previous studies used a constant V_{\max} for each PFT over the year [Baldocchi and Wilson, 2001; Chen et al., 1999; Cramer et al., 2001]. Here we parameterized V_{\max} using albedo- N relation or look-up-table that classified V_{\max} based on PFT and climatic zones, then we varied V_{\max} over the season.

[29] We used the albedo- N relation for closed-canopy temperate and boreal forests where the relation was tested [Hollinger et al., 2010; Ollinger et al., 2008]:

$$N(\%) = (\alpha - 0.02)/0.067 \quad (27)$$

where α is shortwave albedo.

[30] The $N(\%)$ was converted to leaf mass per area, then converted to $N(\text{area})$ based on a global data set of leaf traits [Schulze et al., 1994; Wright et al., 2004]:

$$LMA = 10^{2.24N(\%) - 0.97} \quad (28)$$

$$N(\text{area}) = 10^{-0.52LMA^{0.38}} \quad (29)$$

Finally, the $N(\text{area})$ was converted to $V_{\max}@25C$ (V_{\max}^{25C}) by multiplying by the Nitrogen use efficiency (NUE (Table S2), the ratio of V_{\max}^{25C} to N (g m^{-2}), $\mu\text{molCO}_2 \text{ gN}^{-1} \text{ s}^{-1}$) which was estimated using 723 data points [Kattge et al., 2009]. For open canopies, non-woody vegetation, or PFTs located in arid and tropical climatic zones, we used V_{\max}^{25C} values based on a literature survey that considered both PFT and climatic zones (see section 2.4.4) (Table S2). We assigned vegetation to 'open canopy' if the gap fraction of the zenith direction at peak L is higher than 0.3 (i.e., $\exp(-0.5 L\Omega) > 0.3$).

[31] We considered the seasonal variation of V_{\max}^{25C} [Kosugi et al., 2003; Limousin et al., 2010; Xu and Baldocchi, 2003], as it proved critical to calculate canopy fluxes accurately [Houborg et al., 2009; Muraoka et al., 2010; Reichstein et al., 2003]. We assumed that the seasonal pattern of V_{\max}^{25C} followed the seasonal pattern of L [Houborg et al., 2009]. This pattern has been observed previously in temperate forests [Hikosaka et al., 2007; Kosugi et al., 2003; Muraoka et al., 2010; Wang et al., 2008; Wilson et al., 2001] and Mediterranean forests [Reichstein et al., 2003; Xu and Baldocchi, 2003]. For each individual pixel, we selected the date when MODIS LAI showed the peak value. We

quantified the V_{\max}^{25C} for that date (Peak V_{\max}^{25C}), then calculated V_{\max}^{25C} over the season:

$$V_{\max}^{25C} = a \times \text{Peak}V_{\max}^{25C} + (1 - a) \times \text{Peak}V_{\max}^{25C} \times \frac{L_c - L_{\min}}{L_{\max} - L_{\min}} \quad (30)$$

where L_{\max} , L_{\min} and L_c are maximum, minimum and current leaf area index over the year. We determined the threshold, a , as 0.3 arbitrarily. We calculated the maximum rate of electron transport (J_{\max}^{25C}) using a linear relation with V_{\max}^{25C} [Wullschleger, 1993]:

$$J_{\max}^{25C} = 29.1 + 1.64 \times V_{\max}^{25C} \quad (31)$$

We upscaled the leaf-level V_{\max}^{25C} to the canopy level. The total V_{\max}^{25C} in the canopy ($V_{\max,\text{tot}}^{25C}$) is:

$$V_{\max,\text{tot}}^{25C} = L_c V_{\max}^{25C} \times [1 - \exp(-k_n)] / (k_n) \quad (32)$$

where k_n is the nitrogen extinction coefficient, and we assumed it is same as the beam and scattered beam PAR extinction coefficient (k'_{pb}) for optimal carbon gain [Anten et al., 1995; Hikosaka, 2003].

[32] The sunlit canopy V_{\max}^{25C} is

$$V_{\max,\text{sun}}^{25C} = L_c V_{\max}^{25C} \times \frac{1}{k_n + k_b L_c} [1 - \exp(-(k_n + k_b L_c))] \quad (33)$$

The shaded canopy V_{\max}^{25C} is

$$V_{\max,\text{sh}}^{25C} = V_{\max,\text{tot}}^{25C} - V_{\max,\text{sun}}^{25C} \quad (34)$$

The J_{\max}^{25C} was upscaled to the two-leaf canopy in a same manner as V_{\max}^{25C} . Both $V_{\max,j}^{25C}$ and $J_{\max,j}^{25C}$ for the two leaf canopy ($j = \text{sun or shade}$) was converted to the values at the actual air temperature ($V_{\max,j}$ and $J_{\max,j}$) using a temperature correction function [Kattge and Knorr, 2007].

2.1.5. Two-Leaf Canopy Conductance and Temperature

[33] We used Ball-Berry equation to calculate two-leaf canopy conductance [Ball, 1988]:

$$G_{c,j} = m \frac{A_{c,j} RH}{C_a} + b \quad (35)$$

We fixed the Ball-Berry slope (m) as 10 for C3 species [Collatz et al., 1991; Harley and Baldocchi, 1995; Harley et al., 1992; Xu and Baldocchi, 2003], and 4 for C4 species [Collatz et al., 1992; Hanan et al., 2005].

[34] The enzymatic activity in the photosynthesis models changes with leaf temperature, thus getting the correct leaf temperature is important. We used an analytic solution based on leaf energy balance to calculate two-leaf temperatures [Paw U and Gao, 1988]. However, as the solution requires $G_{c,j}$ as an input variable, which needs T_j for photosynthesis calculation, we iteratively calculated $A_{c,j}$, $G_{c,j}$, and T_j until convergence. The Ball-Berry equation enabled an explicit coupling of photosynthesis and evapotranspiration, although the two 'm' values could be refined [Law et al., 2001].

2.1.6. Evapotranspiration

[35] We used a quadratic form of the Penman-Monteith equation to calculate the two-leaf canopy latent heat flux (λE_j , $j = \text{sun or shade}$) [Monteith, 1965; Paw U and Gao, 1988]. This approach uses the second order Taylor expansion to estimate saturated vapor pressure at the leaf surface using air temperature; on the other hand, the conventional Penman Monteith equation uses the first order Taylor expansion (i.e., linearization). When the temperature difference between the air and leaf is large (e.g., $>5^\circ\text{C}$), the first order approximation can underestimate λE by 10–20% [Paw and Gao, 1988]. Because BESS is designed for global applications, we adopted the quadratic form of the Penman-Monteith equation, which requires exactly the same input variables as the conventional Penman-Monteith equation:

$$a\lambda E_j^2 + b\lambda E_j + c = 0, \quad (36a)$$

where

$$a = \frac{r_a^2}{2[\rho_a C_p \gamma (r_a + r_{c,j})]} \frac{d^2 e_s(T_a)}{dT_a^2} \quad (36b)$$

$$b = -1 - r_a \frac{de_s(T_a)}{dT_a} \frac{1}{\gamma(r_a + r_{c,j})} - \frac{R_{n,j} r_a^2}{\rho_a C_p \gamma (r_a + r_{c,j})} \frac{d^2 e_s(T_a)}{dT_a^2} \quad (36c)$$

$$c = \frac{\rho_a C_p D}{\gamma(r_a + r_{c,j})} + \frac{r_a R_{n,j}}{\gamma(r_a + r_{c,j})} \frac{de_s(T_a)}{dT_a} + \frac{1}{2} \frac{(r_a \times R_{n,j})^2}{\rho_a C_p \gamma (r_a + r_{c,j})} \frac{d^2 e_s(T_a)}{dT_a^2} \quad (36d)$$

where r_a and $r_{c,j}$ are aerodynamic and canopy (j represents sunlit or shade leaf) resistance, respectively. ρ_a is air density. γ is psychrometric constant. $e_s(T)$ is saturated vapor pressure at temperature, T [Henderson-Sellers, 1984]. $R_{n,j}$ is net radiation (j represents sunlit or shade leaf).

[36] The two-leaf λE_j shares all input variables except for $r_{c,j}$ and $R_{n,j}$.

[37] We calculated soil evaporation (λE_{soil}) using a simple equilibrium evaporation model constrained by a soil water stress function. It was reported that soil litter layer substantially controls on the soil evaporation [Baldocchi et al., 2000; Lee and Mahrt, 2004; Wilson et al., 2000]; however, due to the lack of soil litter layer information at global scale, we adopted a simple approach:

$$\lambda E_{soil} = \frac{s}{s + \gamma} (R_{n,soil} - G_{soil}) \times RH^{D/1000} \quad (37)$$

The soil water stress function ($RH^{D/1000}$) was proposed in Fisher et al. [2008]. The $R_{n,soil}$ is net radiation at the soil surface:

$$R_{n,soil} = R_n - (R_{n,Sun} + R_{n,Sh}) \quad (38)$$

G_{soil} is the soil heat flux:

$$G_{soil} = 0.35 \times R_{n,soil} \quad (39)$$

The constant of 0.35 was the mean between its likely limits of 0.2 and 0.5 [Choudhury et al., 1987].

2.2. MODIS-Azure Cloud Computing Service

[38] BESS requires downloading, standardizing and processing approximately 15 terabytes of MODIS data. We built the MODIS-Azure service on the Microsoft Azure cloud computing platform to operate BESS system [Agarwal et al., 2011; Li et al., 2010]. The basic idea is “download MODIS data to the Cloud, process/analyze data in the Cloud, and download results from the Cloud to my PC” (Figure 2). The MODIS-Azure web portal allows 1) submitting job requests and 2) monitoring the processing job status in real-time. One can request the number of virtual machines (1–250 virtual machines currently) depending on the estimated computing needs, which offer highly scalable performance. As shown in Figure 2, after a scientist submits a computation request to the MODIS-Azure system through the Web portal, the request is sent to the Azure system for processing. First, all the required source product data are automatically downloaded from the external MODIS data FTP sites to the Azure storage; the geographic metadata information for all data files are also maintained in Azure storage. Second, all Level 2 MODIS products (swath type) are reprojected into sinusoidal projection as used in Levels 3, 4, and 5 in MODIS Land products. These steps are performed as necessary to satisfy the needs of the science computation and the results are cached in Azure storage. Third, an executable file encoded with the scientists’ computation algorithm is executed at individual virtual machines in parallel to produce the final results. Finally, a download link to the final result data produced by the computation is sent to the scientist in a notification email. Detailed description on the MODIS-Azure system is given by Li et al. [2010].

2.3. Processing MODIS Data

2.3.1. MODIS Atmospheric Products

[39] We used the MODIS-Azure service to grid Level 2 (swaths) MODIS atmospheric products (collection 5). We followed the MODIS Land tile conventions (sinusoidal tiles, each tile is ~ 1200 km by ~ 1200 km) [Wolfe et al., 1998] to standardize the Level 2 MODIS atmospheric products. This step enabled us to co-locate MODIS Land and Atmospheric products. The Level 2 products were gridded for each sinusoidal tile per day using either MOD (Terra) or MYD (Aqua). Primarily, we used MOD (Terra), but when it was not available due to satellite outage, we used MYD (Aqua). The gridded Level 2 MODIS atmospheric products include MO(Y)D04_L2 (aerosol product), MO(Y)D05_L2 (water vapor product), MO(Y)D06_L2 (cloud product), MO(Y)D07_L2 (atmospheric profile product). We determined the sinusoidal tile location first, then the MODIS-Azure system searched all granules that cover the requested tile area using a spatial prescreening technique [Hua et al., 2007] and downloaded the granules from the NASA FTP server (ftp://ladsweb.nascom.nasa.gov/allData/5/). We used an inverse gridding approach [Konecny, 1979; Wolfe et al., 1998] to make the sinusoidal tiles of Level 2 MODIS atmospheric products. The spatial resolution of Level 2 MODIS atmospheric products ranges between 1 km (a portion of the cloud product) and 10 km (aerosol product) (Table 1). We gridded

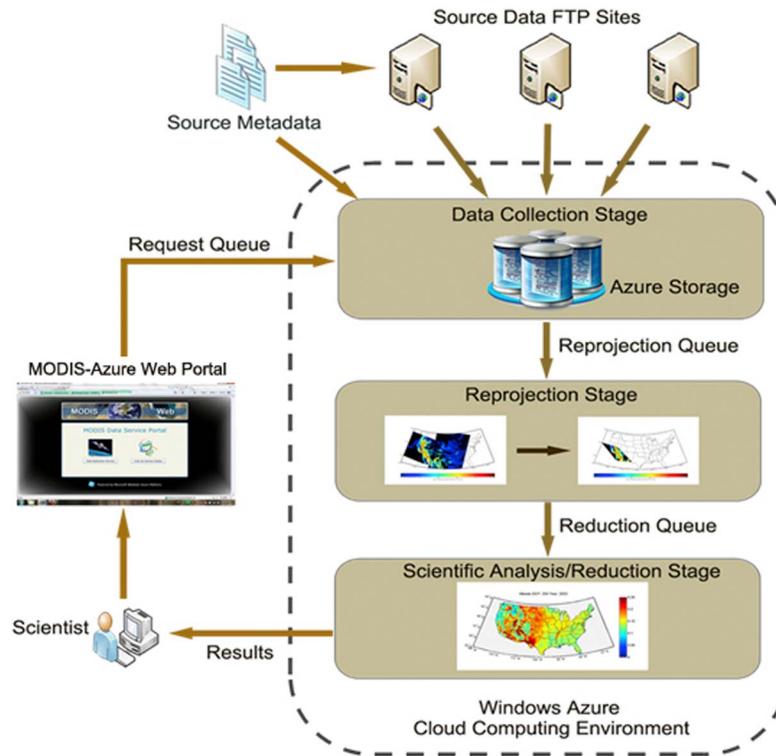

Figure 2. Overview of the MODIS Azure system [Li *et al.*, 2010].

the Level 2 MODIS data with a 1 km resolution for the sinusoidal tiles that include the U.S. and the flux towers that were used in this study, and with a 5 km resolution for the other areas to reduce the data size. The air and dew point temperature were retrieved from MO(Y)D07 only for clear sky days [Houborg *et al.*, 2007; Ryu *et al.*, 2008a]. Under cloudy sky days, we used the NCEP/NCAR reanalysis data (see section 2.4.1) to fill the data gaps. The data gaps in aerosol optical depth (MO(Y)D04) were filled using monthly mean aerosol depth.

2.3.2. MODIS Land Products

[40] We used four gridded MODIS Land products (sinusoidal projection) and one swath Land product (MO(Y)D11_L2) (collection 5) (Table 1). The MO(Y)D11_L2 was gridded as done for the L2 MODIS atmospheric products (see section 2.3.1). For the MODIS LAI product (MCD15A2), we only used the data classified as “Main (RT) method used, best result possible (no saturation)” or “Main (RT) method used with saturation. Good, very usable” in the quality flags. For the MODIS albedo product (MCD43B3), we selected the data classified as “best quality, 75% or more with best full inversions” or “good quality, 75% or more with full inversions” in the data quality flag (MCD43B2). The data gaps in the MCD15A2 and MCD43B2 were filled using the following procedures: 1) if at least three years of data exist with acceptable quality among the five years (2001–2005) for the same date, we used the multiyear mean value to fill the data gap for the specific date; this procedure was suggested in the previous studies [Fang *et al.*, 2008, 2007], 2) if unfilled, we applied the information from moving windows with 2, 5, 10 km size at the same tile and used their mean value to fill the data gap, 3) if unfilled, we

calculated the mean values for each plant functional type, defined in MODIS land cover product (MCD12Q1), at the same tile, and filled the data gaps using the mean values. For the MODIS albedo product, we separated the data gap filling procedures for snow and snow-free areas [Fang *et al.*, 2007]. The MODIS LAI product in rainfall tropical forests was seriously contaminated by clouds [Zhao *et al.*, 2005], thus we selected the maximum leaf area index in a 8-week interval and kept the value over the 8-weeks. The data gaps in MO(Y)D11_L2 under cloudy condition or satellite outages were filled using the NCEP/NCAR reanalysis skin surface temperature data (see section 2.4.1).

2.4. Ancillary Data

2.4.1. NCEP/NCAR Reanalysis 1

[41] For variables not available from the MODIS system, we retrieved information from the NCEP/NCAR Reanalysis

Table 1. The List of MODIS Data Used in This Study^a

Product	Name	Spatial Resolution	Temporal Scale
MO(Y)D04_L2	aerosol	10 km	5 min
MO(Y)D05_L2	water vapor	5 km	5 min
MO(Y)D06_L2	cloud	1 km or 5 km	5 min
MO(Y)D07_L2	atmospheric profile	5 km	5 min
MO(Y)D11_L2	land surface temperature	1 km	5 min
MCD12Q1	land cover	0.5 km	yearly
MCD15A2	leaf area index	1 km	8 day
MCD43B2	BRDF-albedo quality	1 km	16 day
MCD43B3	albedo	1 km	16 day

^aAll Land products are version 5. MOD, Terra; MYD, Aqua; MCD, Terra+Aqua.

1 data (Surface Flux) [Kalnay et al., 1996]. The NCEP data set includes information on air temperature, dew point temperature, land surface temperature, and wind speed. The temperature variables (i.e., air, dew point and land surface) were used to fill the data gaps in MODIS which mostly appeared in the cloudy days. The wind speed data were used to calculate aerodynamic conductance. The spatial coverage of NCEP data includes 88.542N-88.542S, 0E-358.125E with a T62 Gaussian grid (192 × 94 points). Its temporal resolution is 6-hourly. We linearly interpolated the 6-hourly data to match with the time stamp of the MODIS data. To remove the abrupt change on the borders between the coarse pixels, we applied a 3 by 3 moving window average. The NCEP data was resampled using the nearest neighborhood method with the sinusoidal projection at a 1 km resolution.

2.4.2. Global Foliar Clumping Index Map

[42] To consider non-randomness of leaf distribution in space, we used the global foliar clumping index map developed using the multiangle remote sensing data, POLDER 3 [Chen et al., 2005; Pisek et al., 2010]. It offers the clumping index in the growing season at a 6 km resolution. It was resampled using the nearest neighborhood method with the sinusoidal projection at a 1 km resolution.

2.4.3. Global C3 and C4 Distribution Map

[43] To incorporate different ecophysiological processes between C3 and C4 species, we used the global C3 and C4 distribution map [Still et al., 2003]. It offers the proportion of C4 species per pixel at a 1 degree resolution. To remove the abrupt change on the borders between the coarse pixels, we applied a 3 by 3 moving window average. We resampled using the nearest neighborhood method with the sinusoidal projection at a 1 km resolution. The two-leaf model was performed for the C3 and C4 species separately in a pixel, and the sum of relative proportion of C3 and C4 for the pixel determined the GPP and ET at the pixel.

2.4.4. Köppen-Geiger Global Climate Classification Map

[44] To incorporate the information of climate zone into the look up table of the V_{\max}^{25C} where the N-albedo relation was not applied, we used the Köppen-Geiger global climate classification map which represented the average condition between 1951 and 2000 [Kottek et al., 2006]. We used the classification on the main climates that include equatorial, arid, warm temperate, snow, and polar. It provides 0.5 degree resolution. We resampled using the nearest neighborhood method with the sinusoidal projection at a 1 km resolution.

2.5. Temporal Upscaling From Snap-Shots to 8-Day Mean Daily Sums

[45] BESS system quantifies instantaneous GPP and ET first as the radiation components, the main driver of GPP and ET, are derived from the MODIS snap-shots. We upscaled instantaneous GPP and ET estimates to an 8-day mean daily based on a recent study [Ryu et al., 2012]. The potential solar radiation (R_{gPOT}) can be easily calculated with only a few basic pieces of information on the Sun-Earth geometry [Liu and Jordan, 1960]:

$$R_{gPOT} = S_{sc} \times [1 + 0.033 \cos(2\pi t_d/365)] \cos\beta \quad (40)$$

where S_{sc} is the solar constant (1368 W m⁻²), t_d is the day of year, and β is solar zenith angle that is calculated following Michalsky [1988]. The upscaling factor is defined as:

$$SF_d(t) = \frac{1800s \times \lambda E(t)}{\int_d \lambda E(t) dt} \approx \frac{1800s \times R_{gPOT}(t)}{\int_d R_{gPOT}(t) dt} \quad (41)$$

where $SF_d(t)$ is the upscaling factor for a particular day (d) of the year and function of the time t of the instantaneous λE . The 1800s is the number of seconds in 30 min. Then the 8-day mean daily sum λE is:

$$\lambda E_{8day} = \frac{1}{8} \sum_{d=1}^8 \frac{1800s \times \lambda E(t_d)}{SF_d(t_d)} \quad (42)$$

where the time of the snapshot, t_d , may change between one day and another accordingly to the satellite passages.

[46] This temporal upscaling scheme was tested against data from 33 flux towers across seven plant functional types from boreal to tropical climatic zones. The results showed that the upscaled and measured 8-day mean daily sum ET showed a strong linear relation ($r^2 = 0.92$) and small bias (-2.7%) [Ryu et al., 2012]. Furthermore, it was found that the temporal upscaling scheme can be used to upscale instantaneous estimates of GPP and solar irradiance to 8-day mean daily sum estimates as accurately as ET.

2.6. Flux Tower Data and Evaluation of BESS

[47] To test BESS, we used data from 33 flux towers that cover seven plant functional types (PFT) across arctic to tropical climatic zones to test simulations of water and carbon fluxes from BESS (Table 2, the citation for each site is shown in Table S3). The data were extracted from LaThuile 2007 FLUXNET data set v.2 (www.fluxdata.org). We selected at least three sites for each PFT with data gaps less than 30 days per year, and selected one year of measurements per site that was represented by the least of data gaps over the available years. Data gaps were filled using the marginal distribution sampling method in a harmonized and standardized way for the LaThuile 2007 FLUXNET data set [Reichstein et al., 2005].

2.7. Sensitivity Analysis of Evapotranspiration

[48] A non-dimensional relative sensitivity of ET was quantified [Beven, 1979; McCuen, 1974]:

$$S_i = \frac{\partial ET}{\partial V} \frac{V}{ET} \quad (43)$$

where S_i is the relative sensitivity ranged between -1 (negatively highly sensitive) to 1 (positively highly sensitive), ET is the conventional Penman-Monteith equation [Monteith, 1965] to keep simplicity in the differentials, V is the input variable in the Penman Monteith equation such as available energy and canopy conductance. The sensitivity of ET to V is very low as the S_i approaches to the zero.

3. Results

3.1. Evaluation of BESS Against Flux Tower Data

[49] BESS derived solar irradiance ($R_{s,i}$), GPP and ET at 1 km resolution were evaluated against the flux tower data

Table 2. Flux Tower Site Information^a

^aAbbreviations in the plant functional types (PFT) include: CRO: crop, DBF: deciduous broadleaved forest, EBF: evergreen broadleaved forest, ENF: evergreen needle leaved forest. GRA: grassland, MF: mixed forest, WSA: woody savanna. The abbreviations in the climate (in the parenthesis) followed the Köppen-Geiger global climate classification (see the Figure 7 for the definition of the abbreviations).

at the scale of daily sum averaged over an 8-day interval (Figures 3–5). We selected the pixel that included a flux tower, then compared the BESS-derived estimates with the flux tower measurements. There was a strong linear

relation between BESS $R_{s,i}$ and flux tower $R_{s,i}$ ($r^2 > 0.8$) except for the tropical forests (see Table 2 for the list of tropical forests) where the seasonal variation of $R_{s,i}$ was not pronounced (e.g., BR-Ji2 and BR-Sa3, coefficient of

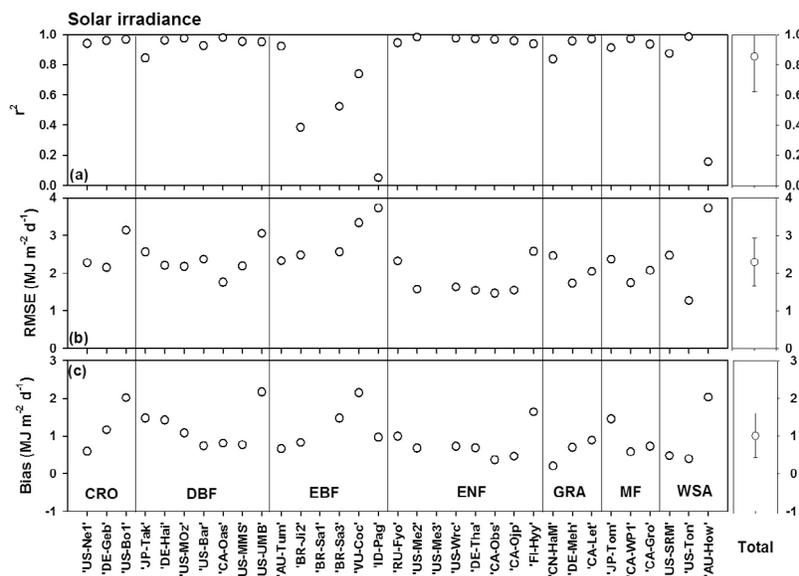

Figure 3. Comparison of 8-day mean daily sum solar irradiance between the 33 flux towers and the BESS.

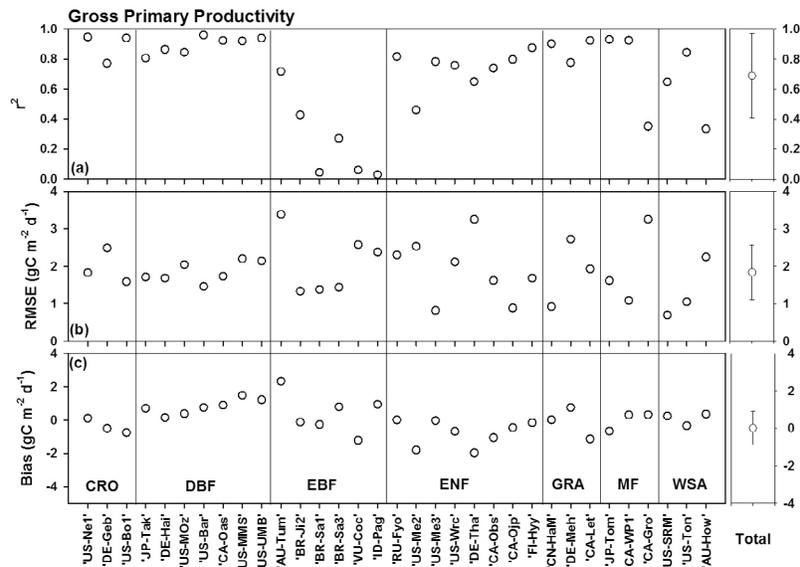

Figure 4. Comparison of 8-day mean daily sum gross primary productivity between the 33 flux towers and the BESS.

variance <15%) or seasonal fires were intense (e.g., ID-Pag and AU-How) (Figure 3). The RMSE varied from 1.2 MJ m⁻² d⁻¹ (U.S.-Ton) to 3.8 MJ m⁻² d⁻¹ (AU-How) with the mean of 2.3 MJ m⁻² d⁻¹. The bias ranged from 0.2 MJ m⁻² d⁻¹ (CN-HaM) to 2.2 MJ m⁻² d⁻¹ (U.S.-Bo1) with the mean of 1 MJ m⁻² d⁻¹.

[50] For the GPP, BESS showed low r^2 (<0.4) for the tropical forests where seasonal pattern of GPP was not pronounced (e.g., BR-Sa1, BR-Sa3, ID-Pag, VU-Coc; the coefficient of variance was <20%) (Figure 4). The average of r^2 over the all sites was 0.69. The RMSE and bias varied from 0.7 (U.S.-SRM) to 3.4 (AU-Tum) gC m⁻² day⁻¹, and

–1.8 (U.S.-Me2) to 2.3 (AU-Tum) gC m⁻² day⁻¹, respectively. The average of RMSE and bias over the all sites were 1.8 and 0.02 gC m⁻² day⁻¹, respectively. BESS underestimated GPP in all evergreen needleleaf forest sites except for the RU-Fyo site; the bias ranged from 0 (RU-Fyo) to –1.96 (U.S.-Me2) gC m⁻² day⁻¹. BESS overestimated GPP of all deciduous broadleaved forest sites; the bias ranged from 0.1 (DE-Hai) to 1.5 (U.S.-MMS) gC m⁻² day⁻¹.

[51] BESS-derived λE showed linear relations with the observed λE from the flux towers ($r^2 > 0.7$) except for the tropical forests (e.g., BR-Sa1, BR-Sa3, ID-Pag, VU-Coc,

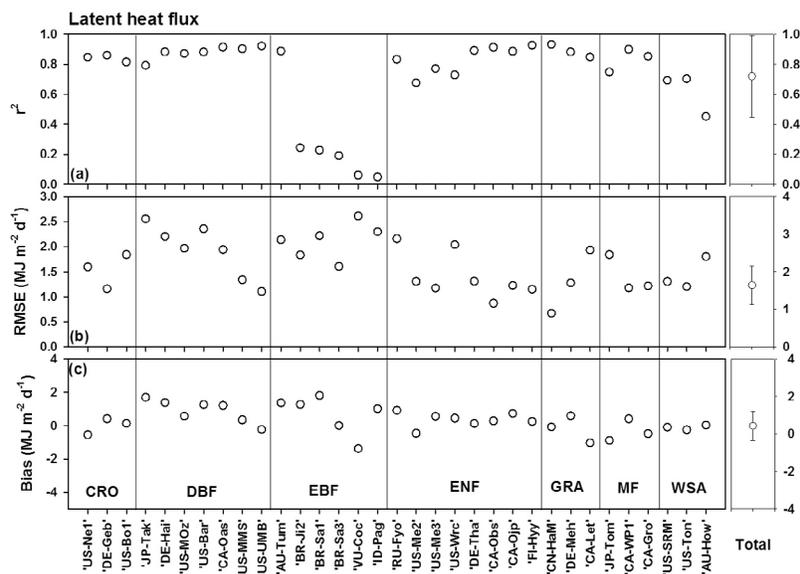

Figure 5. Comparison of 8-day mean daily sum latent heat flux between the 33 flux towers and the BESS.

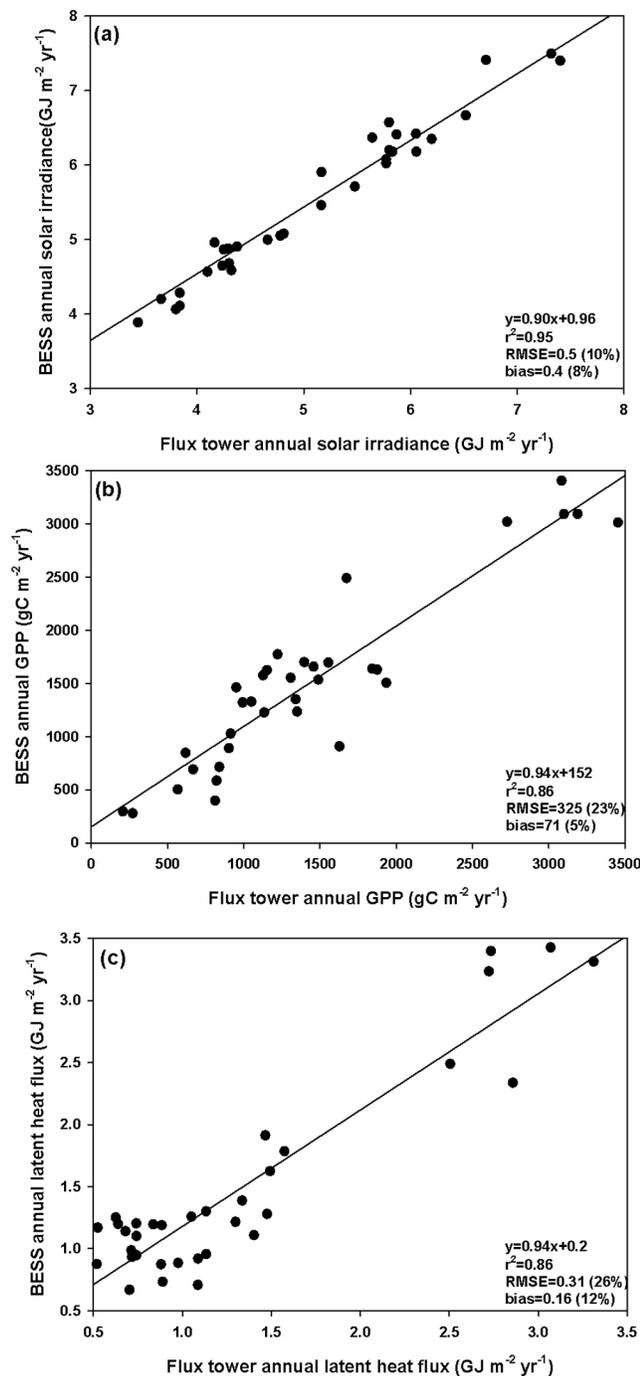

Figure 6. Comparison of (a) annual solar irradiance, (b) gross primary productivity, and (c) latent heat flux between the flux towers and the BESS.

BR-Ji2; coefficient of variance was $<25\%$) (Figure 5). The RMSE and bias varied from 0.7 (CN-HaM) to 2.6 (VU-Coc) $\text{MJ m}^{-2} \text{d}^{-1}$ and -1.4 (VU-Coc) to 1.8 (BR-Sa1) $\text{MJ m}^{-2} \text{d}^{-1}$, respectively. The average of RMSE and bias over the all sites were 1.6 and 0.3 $\text{MJ m}^{-2} \text{d}^{-1}$, respectively.

[52] We evaluated the BESS-derived annual sum of $R_{s,i}$, GPP, and λE against the flux tower data (Figure 6). BESS showed strong linear relations with the flux tower data for

annual $R_{s,i}$, GPP and λE ($r^2 = 0.95$, 86, and 86, respectively). All three variables showed positive biases, with overestimates from BESS. Both relative RMSE and bias were higher for λE than GPP.

3.2. Evaluation of BESS Against Data-Driven Products and Basin Water Balance Data

[53] We compared BESS-derived GPP and ET against the empirical flux-tower-data-driven GPP [Beer *et al.*, 2010] and ET [Jung *et al.*, 2010] products for each bioclimatic zone defined from the Köppen-Geiger global climate classification map. The flux-tower-data driven products were developed by formulating statistical models based on the available FLUXNET data, thus they offer “data-driven” but totally empirical estimates [Jung *et al.*, 2009]. We found that BESS-derived GPP showed an excellent agreement with the GPP estimates of Beer *et al.* [2010] with an r^2 of 0.98, 12% of relative RMSE and 0% of relative bias (Figure 7). BESS-derived ET also showed a very good agreement with the ET estimates of Jung *et al.* [2010] with an r^2 of 0.92, 23% of relative RMSE and 0% of relative bias (Figure 8).

[54] We compared the BESS-derived ET against the basin-scale ET derived using a water balance approach (rainfall minus runoff) as reported by Jung *et al.* [2010]. They calculated the annual mean ET for 112 basins (on average, 15 years) using the discharge data from the Global Runoff Data Centre and the rainfall data from the six different rainfall products (see details in auxiliary material) [Jung *et al.*, 2010]. We used BESS-derived mean annual ET over three years (2001–2003) to compare with the water balance derived ET. BESS derived basin ET showed r^2 of 0.78, RMSE of 168 mm yr^{-1} , and bias of 1.9 mm against the water balance derived ET (Figure 8c). For comparison, the data-driven mean annual ET that covered the same period with water-balance ET showed r^2 of 0.92, RMSE of 149 mm yr^{-1} , and bias of 17 mm yr^{-1} of bias against the water balance derived ET [Jung *et al.*, 2010].

3.3. Sensitivity Analysis on BESS-Derived GPP and ET

[55] We performed a simple sensitivity analysis for BESS-derived GPP and ET over the global land in July, 2003 (Figure 9). We selected five variables that included solar irradiance ($R_{s,i}$), leaf area index (L_c), $V_{\text{max}}^{25\text{C}}$, vapor pressure deficit (D), and wind speed. We changed the values of each variable by $\pm 30\%$ while keeping the other four variables, and compared the BESS outputs. The consistent relative change for each variable offered all outputs comparable and we assumed the natural variability is well within the range of $\pm 30\%$ of the variables. BESS-derived GPP was most sensitive to the L_c , and next $V_{\text{max}}^{25\text{C}}$. A 30% change in L_c was associated with a $\sim 25\%$ change in GPP. A 30% change in $V_{\text{max}}^{25\text{C}}$ was associated with a $\sim 15\%$ change in GPP. ET was most sensitive to $R_{s,i}$, and next L_c . The 30% change in $R_{s,i}$ was associated with a $\sim 20\%$ change in ET. For both GPP and ET, BESS was less sensitive to D and wind speed.

[56] The sensitivity of ET to available energy and canopy conductance was investigated (see 2.7) in July 2003 (Figure 10). The ET was highly sensitive to the available energy in the rainfall forests in Amazon, Congo, and Indonesia. The ET was highly sensitive to the canopy conductance in dry region such as mid-west U.S., Spain, Australia and Central Asia.

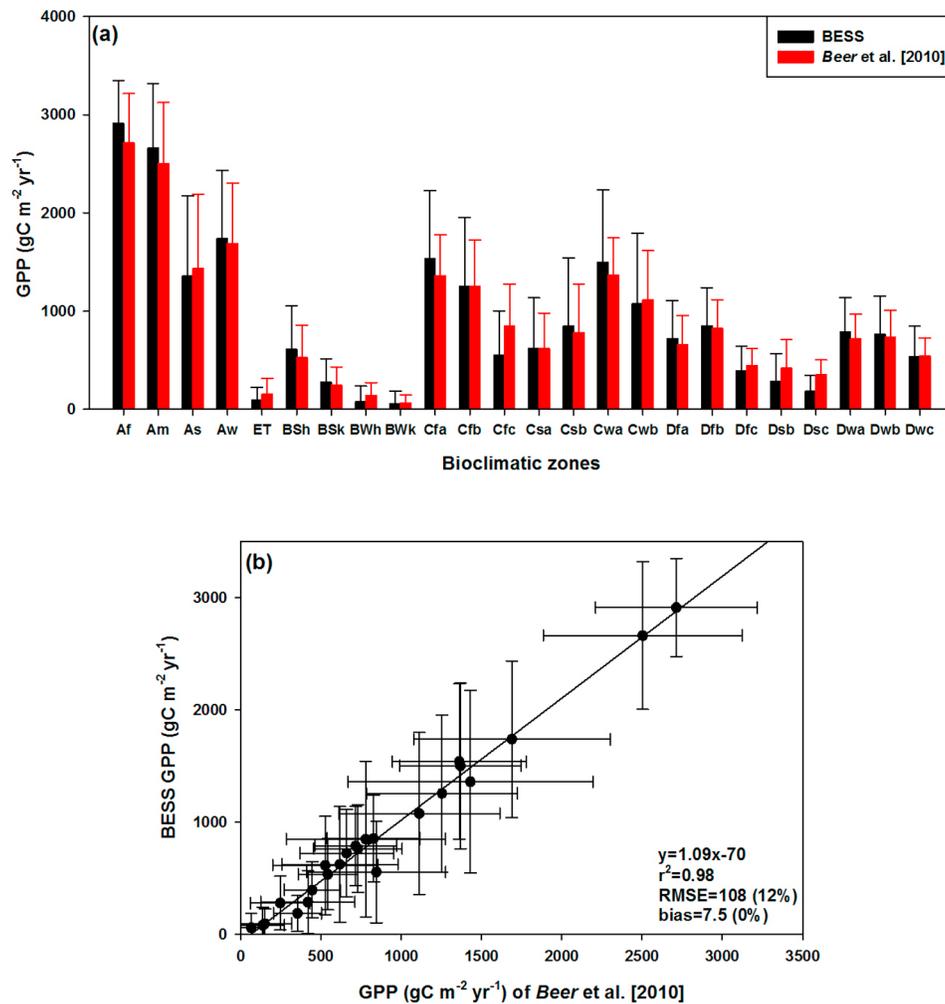

Figure 7. Comparison of gross primary productivity between *Beer et al.* [2010] and the BESS across bioclimatic zones classified by the Köppen-Geiger global climate classification map (see section 2.4.4). The abbreviations for the bioclimatic zones are as follows: Af, equatorial, fully humid; Am, equatorial, monsoonal; As, equatorial, summer dry; Aw, equatorial, winter dry; BWh, hot arid desert; BSk, cold arid steppe; BSh, hot arid steppe; Cfa, humid, warm temperate, hot summer; Cfb, humid, warm temperate, warm summer; Cfc, humid, warm temperate, cool summer; Csa, summer dry, warm temperate, warm summer; Csb, summer dry, warm temperate, warm summer; Cwa, winter dry, warm temperate, hot summer; Cwb, winter dry, warm temperate, warm summer; Dfa, snow, humid, hot summer; Dfb, snow, humid, warm summer; Dfc, snow, humid, cool summer; Dsb, snow, summer dry, warm summer; Dsc, snow, summer dry, cool summer; Dwa, snow, winter dry, hot summer; Dwb, snow, winter dry, warm summer; Dwc, snow, winter dry, cool summer; ET, polar tundra.

3.4. Global and Yearly Estimates of Terrestrial GPP and ET

[57] We quantified the mean annual land GPP over the three years (2001–2003) as $118 \pm 26 \text{ PgC yr}^{-1}$ (or $938 \pm 206 \text{ gC m}^{-2} \text{ yr}^{-1}$) (Figure 11a). To estimate the error bounds, we calculated the mean RMSE between flux tower and BESS for each PFT, assigned the RMSE to the global land which was classified with the same PFT, then quantified the RMSE at global scale. The global annual GPP varied 115, 117, 122 PgC yr^{-1} across the three years. The annual mean global land ET over the same period was $500 \pm 104 \text{ mm yr}^{-1}$ (equivalent to $63,000 \pm 13,100 \text{ km}^3 \text{ yr}^{-1}$) (Figure 11b). The uncertainty was estimated as done in GPP.

The global land ET varied 498, 498, 504 mm yr^{-1} for the three years. For the unit conversion in GPP (PgC yr^{-1} to $\text{gC m}^{-2} \text{ yr}^{-1}$) and ET (mm yr^{-1} to $\text{km}^3 \text{ yr}^{-1}$), we used the global land area as $1.26 \times 10^8 \text{ km}^2$ determined from MODIS land cover product. We excluded urban, Greenland, Arctic and Antarctic regions in the land area estimation.

4. Discussion

4.1. Efficacy of BESS

[58] The mechanistic, coupled biophysical model produced reliable estimates of GPP and ET against flux tower data (Figures 4–6), data-driven products (Figures 7 and 8),

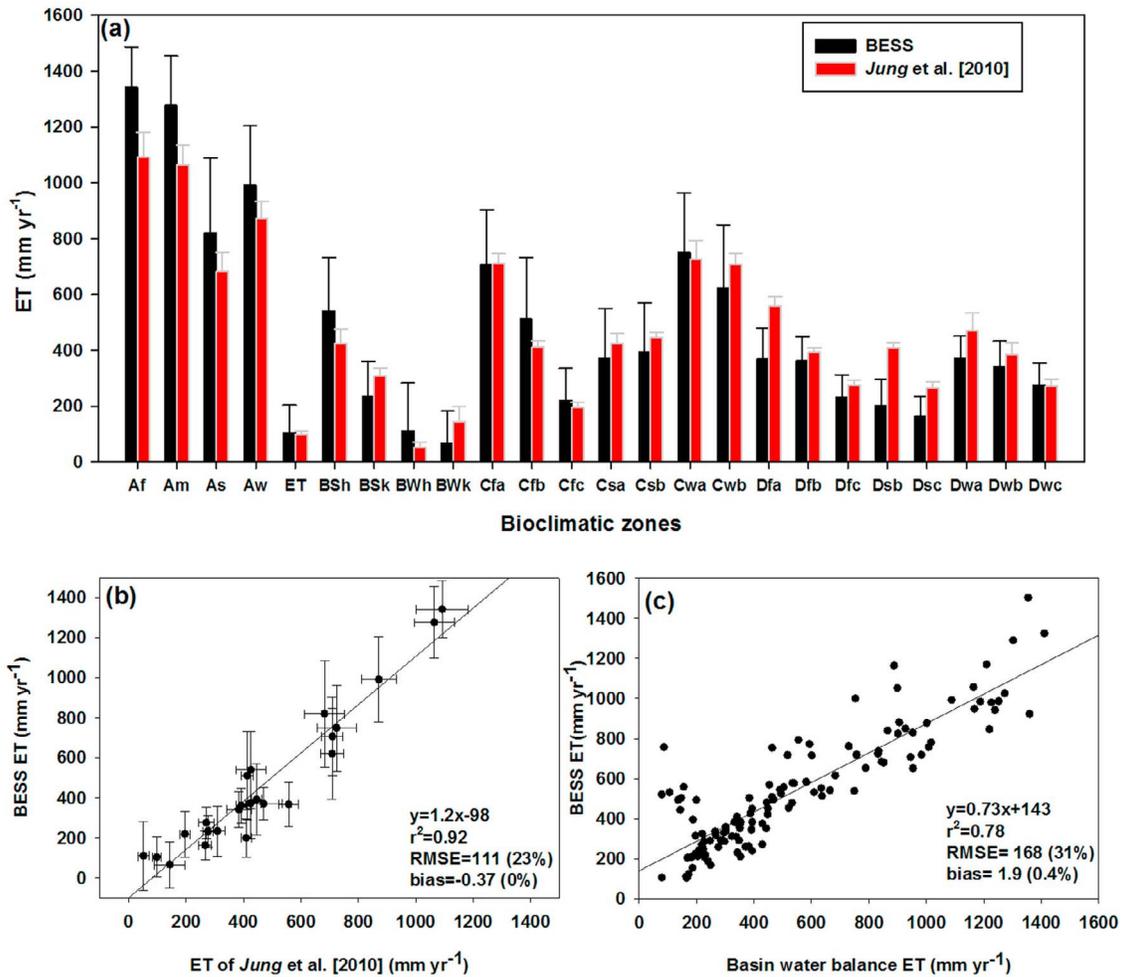

Figure 8. (a and b) Comparison of evapotranspiration between *Jung et al.* [2010] and the BESS across bioclimatic zones classified by the Köppen-Geiger global climate classification map (see section 2.4.4). (c) Comparison of evapotranspiration between the water-balance derived evapotranspiration from global 112 basins (see section 3.2) and the BESS. The abbreviations for the bioclimatic zones are same as in Figure 6.

and basin water balance derived ET (Figure 8c). The formulation of BESS model was entirely independent from flux tower data, which contrast with previous empirical studies that used flux tower data to calibrate key parameters [Yuan *et al.*, 2010; Zhang *et al.*, 2010] or to apply machine-learning technique [Beer *et al.*, 2010; Jung *et al.*, 2010; Xiao *et al.*, 2010]. The success of BESS demonstrates that the advancements in remote sensing, micrometeorology, and ecophysiology enable us to develop a globally applicable model based on first principles, which was discouraged a generation ago due to the concerns about garbage-in and garbage-out [de Wit, 1970].

[59] We note that BESS did not explicitly include a soil moisture effect, which is a major factor that limits GPP and ET in water-limited ecosystems [Ciais *et al.*, 2005; Rambal *et al.*, 2003; Ryu *et al.*, 2008b; Scott *et al.*, 2010; Xu and Baldocchi, 2004], and evaporation from intercepted rainfall in the canopy, which could be $\sim 20\%$ of rainfall in forests [Miralles *et al.*, 2010]. Why did BESS perform well in spite

of the lack in the two terms? BESS assumed that the soil moisture stress is reflected in the seasonal pattern of leaf area index, which in turn influences the seasonal pattern of V_{\max}^{25} (see section 2.1.4). We found that this assumption enabled us to capture the seasonal water-limiting effects in most seasonally dry ecosystems such as U.S.-Ton, U.S.-SRM, and AU-How sites. BESS-derived GPP and ET in dry regions were comparable with the data-driven products (Figures 7b and 8b). However, this assumption did not work where MODIS incorrectly quantified leaf area index in semi-arid pine forests that have low seasonality of leaf area index with low annual rainfall and cold winter temperatures (e.g., U.S.-Me2, 535 mm mean annual precipitation [Thomas *et al.*, 2009]; see section 4.2). The evaporation from intercepted rainfall was not explicitly considered in BESS. However, in the wet canopy where intercepted rainfall is dominant, canopy conductance tends to be high (say, $>20 \text{ mm s}^{-1}$) [Baldocchi *et al.*, 1997]. Consequently, canopy transpiration calculated by BESS likely reflects the

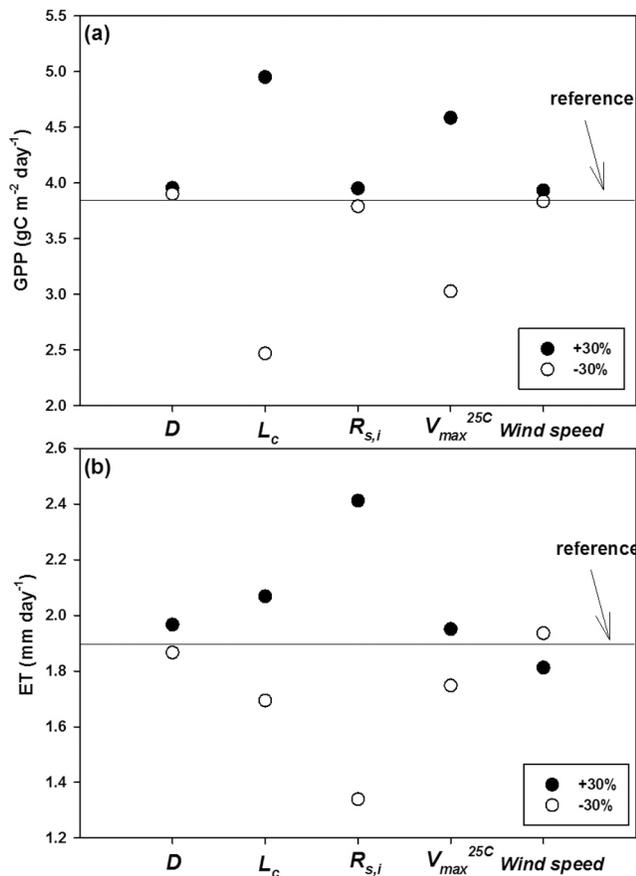

Figure 9. Sensitivity analysis of the BESS. Each variable was changed $\pm 30\%$, and the output from the BESS for (a) gross primary productivity and (b) evapotranspiration was compared. D , vapor pressure deficit; L_c , leaf area index; $R_{s,i}$, incoming solar irradiance; V_{\max}^{25C} , maximum carboxylation rate at 25C.

evaporation by the intercepted rainfall at least to some degree. These limitation in BESS model proved not to have a detrimental effect on the model performance, as the model seems to work well at a number of scales against measurements.

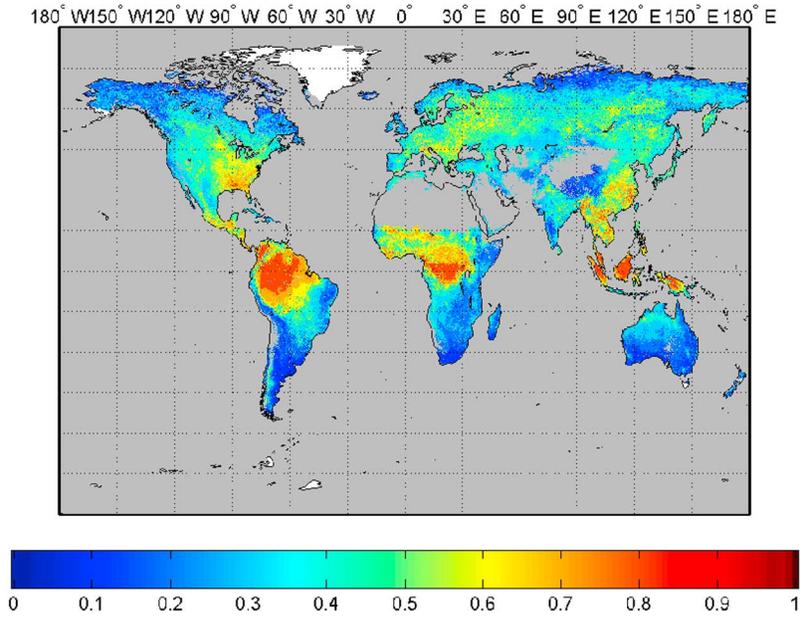

[60] We made BESS most sensitive to the variables that we can quantify reliably. We determined the variables as the atmospheric and canopy radiation components as it is possible to estimate incoming radiation and canopy structure variables such as leaf area index and clumping index from space. We found that BESS offered robust estimates of solar irradiance, except for the tropical regions that experienced intensive biomass burning (e.g., ID-Pag and AU-How sites) (Figures 3 and 6a). We believe the integration of atmosphere and sunlit-shade canopy radiative transfers at the same spatial (1–5 km) and temporal (instantaneous) resolutions greatly reduced uncertainties related with nonlinear processes in canopy fluxes. Previous studies have illustrated scale-mismatches at both spatially (e.g., coarse resolution of solar irradiance with high resolution canopy properties) and temporally (e.g., use of daily to monthly mean solar irradiance) [Fisher *et al.*, 2008; Mu *et al.*, 2007; Yuan *et al.*, 2010;

Zhao *et al.*, 2005]. Leaf area index was the most important variable that controlled canopy radiative transfer, and we found that the MODIS LAI was reliable at regional and seasonal scales although several important limitations were identified (see section 4.2). The clumping index that modifies canopy radiative transfer and the proportion of sunlit and shade leaves has been mostly ignored in global carbon and water flux studies even though field level studies have suggested the importance of clumping index in canopy modeling studies [Baldocchi, 1997; Baldocchi *et al.*, 2002, 1985; Chen *et al.*, 1999; Norman and Jarvis, 1974]. We compared the global GPP and ET between random canopy (clumping index = 1) and clumped canopy for the year 2002. The clumped canopy reduced GPP (1.5 PgC yr⁻¹) and increased ET (1,888 km⁻³ yr⁻¹) compared to the random canopy ($\Omega = 1$). The difference in GPP was comparable to the carbon emissions caused by deforestation and forest degradation globally (1.2 PgC yr⁻¹) [van der Werf *et al.*, 2009] and caused by global transportation sector (1.7 PgC yr⁻¹) [Kahn Ribeiro *et al.*, 2007], thus incorporating the foliar clumping effect into the carbon cycle model is important to reduce uncertainty in the global carbon cycle. The V_{\max}^{25C} was the second most important variable that controls GPP (Figure 9a). To estimate the values of V_{\max}^{25C} , we applied emerging ecological scaling rules that included the nitrogen concentration-albedo relationships [Hollinger *et al.*, 2010; Ollinger *et al.*, 2008] and the nitrogen concentration-leaf mass area relationships [Reich *et al.*, 1997; Wright *et al.*, 2004] for the closed canopy in boreal and temperate forests (see section 2.1.4). For the other land covers, we used the values of V_{\max}^{25C} from the literature survey by considering both climate zones and plant functional types (Table S2). Finally we applied seasonality of V_{\max}^{25C} which tends to reflect seasonal environmental stress [Muraoka *et al.*, 2010; Wilson *et al.*, 2001; Xu and Baldocchi, 2003]. We believe deducing V_{\max}^{25C} by integrating the experimental evidences mentioned above enabled us to estimate GPP accurately.

[61] It has been reported that vapor pressure deficit from global reanalysis data introduced a major source of uncertainties in the MODIS GPP product [Heinsch *et al.*, 2006; Zhao *et al.*, 2006]. That was because the vapor pressure deficit directly controlled canopy conductance in the MODIS GPP algorithm. Physiologically, GPP is sensitive to both vapor pressure deficit and soil moisture availability to roots. For MODIS GPP, sensitivity to vapor pressure deficit was increased to represent moisture limitations to GPP because reliable data on the spatial water availability were not available. In BESS, we intended to avoid the dependence of GPP on the vapor pressure deficit by fixing the ratio of internal leaf and ambient CO₂ concentration (see section 2.1.4). In fact, BESS-derived GPP and ET were not highly sensitive to the vapor pressure deficit (Figure 9). Zhao *et al.* [2006] reported that different sources of coarse global reanalysis meteorological data could cause substantial differences (>20 PgC yr⁻¹) in the global GPP estimates based on the MODIS GPP algorithm. BESS avoided this issue by directly calculating meteorological variables from MODIS atmospheric products at high spatial resolution (1–5 km).

[62] The process-oriented approach enabled us to investigate what controls ET at the global scale (Figure 10). In situ data revealed that ET was highly correlated with net

(a) Sensitivity of ET to available energy Year: 2003, Mon: 7

(b) Sensitivity of ET to canopy conductance Year: 2003, Mon: 7

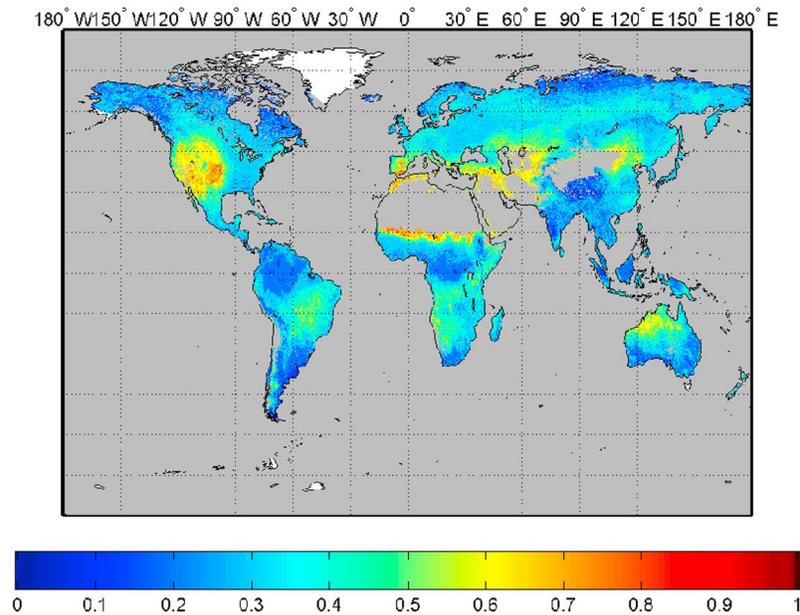

Figure 10. Global maps of sensitivity of ET to (a) available energy and (b) canopy conductance in July 2003. The sensitivity ranges between 0 (less sensitive) to 1 (positively highly sensitive). See section 2.7 for the calculation of the sensitivity.

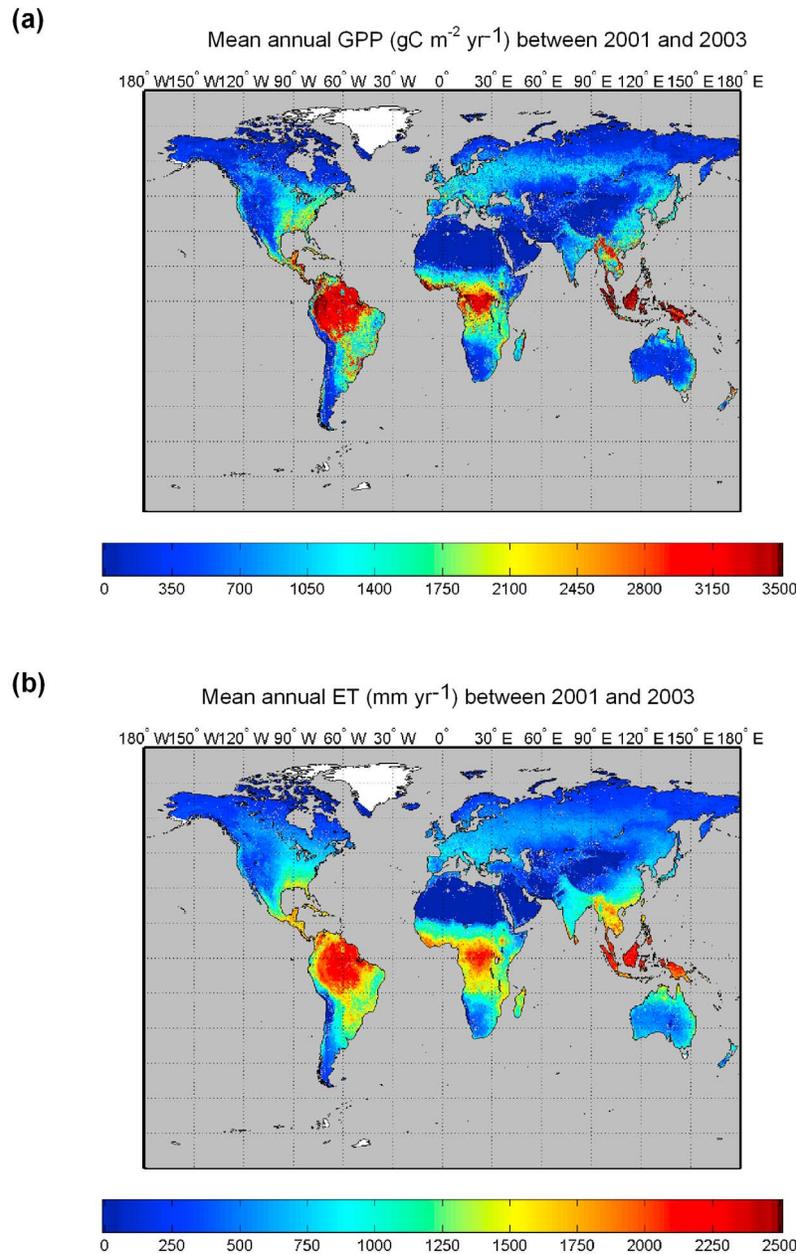

Figure 11. Global maps of (a) gross primary productivity and (b) evapotranspiration.

radiation in rain forests of Brazil whereas the correlation was less in southern Brazil due to water stress during the dry period [Hasler and Avissar, 2007]. This spatial gradient was well captured by BESS (Figure 10a). The sensitivity of ET to the available energy was positively high (>0.8) at the rain forests in Brazil and the sensitivity decreased along the southeast direction toward the cerrado, the tropical savanna ecoregion in Brazil. The sensitivity of ET to canopy conductance was fairly high (>0.5) in the cerrado region where dry winter season is pronounced between May and Oct.

4.2. Sources of Uncertainty in BESS

[63] The sensitivity analysis revealed that BESS-derived GPP was most sensitive to L_c (Figure 9). We found that

inaccuracies in MODIS LAI led to major uncertainties at several sites. For example, the BESS showed substantial overestimation of GPP and ET at the AU-Tum site (see Figures 3 and 4). The peak L_c of MODIS LAI was twofold higher than the in situ L_c in this site (5 vs 2.5) [Leuning *et al.*, 2005; Strahler *et al.*, 2008]. It has also been reported that MODIS LAI overestimated L_c in eastern Australian open forests and woodlands [Hill *et al.*, 2006]. Next, seasonality of MODIS LAI for evergreen needleleaf forest types was exaggerated at most sites. For example, the in situ L_c in the Me2 site varied 2.6–3.5 over the year (Law, this study), but the MODIS LAI ranged 0–4. The MODIS LAI for the RU-Fyo site showed 0–4.8 over the year, but the field observation showed 2.5–3.5 over the year (A. Varlagin,

personal communication, 2010). The leaf area index of 0 in evergreen forests is unrealistic. The incorrect representation of phenology caused a simulated delay from BESS in the increase of GPP in the spring at the U.S.-Me2 and RU-Fyo sites. We found that the underestimated L_c during spring or autumn caused the underestimation of BESS-GPP in most evergreen needleleaf forest sites (Figure 4c). In the tropics, the selected MODIS LAI data that passed the quality check were few (see section 2.3.2) and provided a noisy signal and therefore a correction to L_c was unavoidable (i.e., keeping the peak L_c value over a 8-weeks period, see section 2.3.2). BESS-derived ET is coupled with GPP (equation (35)), and thus the uncertainty in GPP will be translated to uncertainties in ET. The sensitivity analysis revealed that BESS-derived ET was most sensitive to the $R_{s,i}$ (Figure 9b). Our $R_{s,i}$ model was generally reliable (relative RMSE and bias were 10% and 8%, respectively, see Figure 6a) although improvements were required in the tropics (see section 4.1); thus the uncertainty of L_c , which was the second most sensitive variable (Figure 9b), is likely to contribute a major source of uncertainty in the ET calculation. However, we note that the $R_{s,i}$ model in BESS overestimated R_s during intensive biomass burning events in tropical forests (e.g., ID-Pag [Hirano *et al.*, 2007] and AU-How [Kanniah *et al.*, 2010]). We speculate that the characterization of aerosol properties used in the BESS needs improvement. Last, BESS did not consider complex terrain and heterogeneity of landscapes in a pixel, which might cause substantial biases in land surface radiation and energy balances [Baldocchi *et al.*, 2005; Giorgi and Avissar, 1997; Ryu *et al.*, 2008a]. We note that the uncertainty sources in input data and the gap-filling processes (see sections 2.3.1 and 2.3.2) can influence the results in the sensitivity analysis. In particular, a substantial data gap of MODIS data in the tropics and the way to fill the data gaps might impact the results in the sensitivity analysis substantially. We leave the detailed analysis on the impacts of the uncertainty sources on the sensitivity analysis for the next study.

4.3. Global Terrestrial Estimates of GPP and ET

[64] The global estimates of GPP and ET are still uncertain as reports varied between 107 and 167 PgC yr⁻¹ [Cramer *et al.*, 2001; Knorr and Heimann, 2001], 123 PgC yr⁻¹ [Beer *et al.*, 2010], 129 PgC yr⁻¹ [Demarty *et al.*, 2007], 133 PgC yr⁻¹ [Ruimy *et al.*, 1996], 109 PgC yr⁻¹ [Zhao *et al.*, 2005], and 111 PgC yr⁻¹ [Yuan *et al.*, 2010]. We quantified the mean global GPP between 2001 to 2003 as 118 ± 26 PgC yr⁻¹. Recently, Beer *et al.* [2010] quantified the global GPP as 123 ± 8 PgC yr⁻¹ based on merging global flux tower data (i.e., “data-driven” approach). Interestingly, we found that BESS showed an excellent agreement with the Beer *et al.* (2010) across bioclimatic zones (Figure 7). Even if the two approaches were totally different (i.e., empirical vs process-based), they showed convergent estimates of global GPP. The global land ET is also highly uncertain [Lettenmaier and Famiglietti, 2006]. For example, a modeling study assumed a constant global land ET of 527 mm yr⁻¹ without spatial and temporal variation of ET [Wentz *et al.*, 2007]. A range of global land ET was reported such as 613 mm yr⁻¹ [Fisher *et al.*, 2008], 286 mm yr⁻¹ [Mu

et al., 2007], 410 mm yr⁻¹ [Yuan *et al.*, 2010], 550 mm yr⁻¹ (65,000 km³ yr⁻¹) [Jung *et al.*, 2010], and 539 mm yr⁻¹ [Zhang *et al.*, 2010]. A recent ET synthesis study reported that the ensemble means of diagnostic models, land surface models, reanalysis models, IPCC AR4 models showed 606 mm yr⁻¹, 544 mm yr⁻¹, 631 mm yr⁻¹ and 602 mm yr⁻¹, respectively [Mueller *et al.*, 2011]. Our global land ET estimate between 2001 and 2003 was 500 ± 104 mm yr⁻¹ (equivalent to 63,000 ± 13,100 km³ yr⁻¹). We note that our global ET estimate included deserts and alpine regions in Himalaya whereas some other studies only included vegetated land area which differs depending on the land cover product used. Thus reporting global ET as km³ yr⁻¹ unit is highly recommended to avoid any confusion. Our global ET estimate (63,000 km³ yr⁻¹) was comparable from 65,000 km³ yr⁻¹ [Jung *et al.*, 2010] and 65,500 km³ yr⁻¹ [Oki and Kanae, 2006]. BESS-derived ET showed good agreement with the data-driven global ET product across bioclimatic zones and basin-level water balance ET [Jung *et al.*, 2010] (Figure 8). A systematic inter-comparison project across available GPP and ET models is warranted to identify where the models agree and disagree and how to improve them. The process-based BESS which couples two-leaf energy balance, canopy nitrogen, GPP and ET could offer mechanistic interpretation of the disagreement in the models, which is unlikely to be done in empirical approaches.

5. Summary and Conclusions

[65] In this study, we described and evaluated the mechanistic, coupled biophysical model, BESS. BESS coupled atmospheric and canopy radiative transfer processes, two-leaf photosynthesis, energy balance, and evapotranspiration using MODIS. The integration of biophysical processes with some assumptions that included soil water deficit is embedded inside the variations of leaf area index offered robust estimates of GPP and ET compared with the flux tower data, data-driven products, and basin-level water balance ET. Because we purposely increased sensitivity of BESS to leaf area index and solar irradiance, they were the most important variables that control GPP and ET, respectively. Over the three year period between 2001 and 2003, BESS quantified the global mean annual GPP and ET as 118 ± 26 PgC yr⁻¹ and 500 ± 104 mm yr⁻¹ (equivalent to 63,000 ± 13,100 km³ yr⁻¹), respectively. BESS enabled us to investigate the sensitivity of ET to environmental and biological variables, which well captured the gradient of wetness from rain forests to seasonally drought forests in the Amazon. As BESS offers relatively high spatial resolution over the world (1- to 5-km resolution), we expect that BESS could be useful in local to the global applications such as climate research, water resources management, and identifying spots for solar harvesting.

Appendix A

[66] Appendix A includes the nomenclature and values used in this study. Table A1 includes symbols, their definitions, and if available, their values.

Table A1. Nomenclature and Values

Symbols	Definition	Value (or Derivation)
ρ_{cbP}	canopy reflectance for beam PAR	MODIS black-sky PAR albedo calculated with solar zenith angle and aerosol optical thickness
ρ_{cdP}	canopy reflectance for diffuse PAR	MODIS white-sky PAR albedo calculated with solar zenith angle and aerosol optical thickness
ρ_{cbN}	canopy reflectance for beam NIR	MODIS black-sky NIR albedo calculated with solar zenith angle and aerosol optical thickness
ρ_{cdN}	canopy reflectance for diffuse NIR	MODIS white-sky NIR albedo calculated with solar zenith angle and aerosol optical thickness
ρ_{sP}	soil reflectance for PAR	Table S1
ρ_{sN}	soil reflectance for NIR	Table S1
σ_{PAR}	leaf scattering coefficient for PAR	Table S1
σ_{NIR}	leaf scattering coefficient for NIR	Table S1
Q_{Pijk}	absorbed photosynthetically active radiation ($\mu\text{mol m}^{-2} \text{s}^{-1}$); $i = b$ for beam, and $i = d$ for diffuse; $j = Sun$ for sunlit leaf, and $j = Sh$ for shade leaf; $k = \downarrow$ for from sky to land direction, and $k = \uparrow$ for land to sky direction	equations (10) and (11)
Q_{Nijk}	absorbed NIR radiation (W m^{-2}); $i = b$ for beam, and $i = d$ for diffuse; $j = Sun$ for sunlit leaf, and $j = Sh$ for shade leaf; $k = \downarrow$ for from sky to land direction, and $k = \uparrow$ for land to sky direction	equations (18) and (19)
Q_{Lj}	absorbed longwave radiation (W m^{-2}); $j = Sun$ for sunlit leaf, and $j = Sh$ for shade leaf	equations (20) and (21)
α	shortwave albedo	MCD43B3 albedo calculated with solar zenith angle and aerosol optical thickness
$V_{\text{max}, j}^{25C}$	maximum carboxylation rate at 25C ($\mu\text{mol m}^{-2} \text{s}^{-1}$); $j = Sun$ for sunlit leaf, $j = Sh$ for shade leaf, and $j = tot$ for the entire canopy; no indication of j is leaf	see section 2.1.4
$J_{\text{max}, j}^{25C}$	maximum electron transfer rate at 25C ($\mu\text{mol m}^{-2} \text{s}^{-1}$); $j = Sun$ for sunlit leaf, $j = Sh$ for shade leaf, and $j = tot$ for the entire canopy; no indication of j is leaf	see section 2.1.4
$A_{c, j}$	canopy photosynthesis; $j = Sun$ for sunlit leaf, and $j = Sh$ for shade leaf	equation (22)
$A_{l, j}$	light limited rate of CO_2 assimilation; $j = Sun$ for sunlit leaf, and $j = Sh$ for shade leaf	equation (23)
$A_{v, j}$	Rubisco limited rate of CO_2 assimilation; $j = Sun$ for sunlit leaf, and $j = Sh$ for shade leaf	equation (24)
$A_{s, j}$	capacity for the export or utilization of the products of photosynthesis for C3 species, and CO_2 limited flux for C4 species; $j = Sun$ for sunlit leaf, and $j = Sh$ for shade leaf	equation (25)
p_i	intercellular CO_2 partial pressure (Pa)	C3: $0.7 \times [\text{CO}_2] \times 10^{-6} \times P$ and C4: $0.4 \times [\text{CO}_2] \times 10^{-6} \times P$, where $[\text{CO}_2]$ is atmospheric CO_2 concentration (370 ppm) and P is atmospheric pressure (Pa)
C_a	ambient atmospheric CO_2 concentration	370 ppm
P	atmospheric pressure (Pa)	MOD07
Γ_{*j}	CO_2 compensation point of photosynthesis in the absence of mitochondrial respiration (Pa); $j = Sun$ for sunlit leaf, and $j = Sh$ for shade leaf	3.69 at 25C [<i>de Pury and Farquhar, 1997</i>]; see <i>de Pury and Farquhar</i> [1997, Table 4] to convert the value at the actual temperature
$K_{C,j}$	Michaelis-Menten constant of Rubisco for CO_2 (Pa)	40.4 at 25C [<i>de Pury and Farquhar, 1997</i>]; see <i>de Pury and Farquhar</i> [1997, Table 4] to convert the value at the actual temperature
$K_{O,j}$	Michaelis-Menten constant of Rubisco for O_2 (Pa)	24800 at 25C [<i>de Pury and Farquhar, 1997</i>]; see <i>de Pury and Farquhar</i> [1997, Table 4] to convert the value at the actual temperature
O	oxygen partial pressure (Pa)	20500 at 25C [<i>de Pury and Farquhar, 1997</i>]; see <i>de Pury and Farquhar</i> [1997, Table 4] to convert the value at the actual temperature
$R_{c,j}$	canopy respiration; $j = Sun$ for sunlit leaf, and $j = Sh$ for shade leaf	equation (26)
E_a_{KC}	activation energy for K_c	59400 [<i>de Pury and Farquhar, 1997</i>]
R	universal gas constant ($\text{J mol}^{-1} \text{K}^{-1}$)	8.314
m	Ball-Berry slope (equation (35))	C3, 10; C4, 4
b	Ball-Berry offset (equation (35))	C3, $10^4 \mu\text{mol m}^{-2} \text{s}^{-1}$; C4, $4 \times 10^4 \mu\text{mol m}^{-2} \text{s}^{-1}$ [<i>Houborg et al., 2009</i>]
r_a	aerodynamic resistance (s m^{-1})	NCEP wind speed; canopy height (Table S1)
$r_{c,j}$	canopy resistance for water vapor (s m^{-1}); $j = Sun$ for sunlit leaf, and $j = Sh$ for shade leaf	Ball-Berry equation (equation (35))
G_a	aerodynamic conductance (m s^{-1})	$1/r_a$
$G_{c,j}$	canopy conductance (m s^{-1}); $j = Sun$ for sunlit leaf, and $j = Sh$ for shade leaf	Ball-Berry equation (equation (35))
$N(\%)$	nitrogen concentration (mg g^{-1})	equation (27)
$N(\text{area})$	nitrogen content (g m^{-2})	equation (29)
LMA	leaf mass per area (g m^{-2})	<i>Wright et al. [2004]</i>

Table A1. (continued)

Symbols	Definition	Value (or Derivation)
s	rate of change of saturation vapor pressure with air temperature (Pa K ⁻¹)	MOD07
γ	psychrometric constant (Pa K ⁻¹)	MOD07
λ	latent heat of vaporization (J kg ⁻¹)	MOD07
RH	relative humidity of the air (0–1)	MOD07
λE	latent heat flux (W m ⁻²)	see section 2.1.6
σ	Stefan-Boltzmann constant (W m ⁻² K ⁻⁴)	5.67×10^{-8}
ϵ_a	emissivity of the air	Prata [1996]
ϵ_l	emissivity of the leaf	0.98
ϵ_s	emissivity of the soil	0.94
c_p	specific heat of the air (J kg ⁻¹ K ⁻¹)	MOD07
ρ_a	air density (kg m ⁻³)	MOD07
T_{Sun}	sunlit leaf temperature (K)	see section 2.1.5
T_{Sh}	shade leaf temperature (K)	see section 2.1.5
T_a	air temperature (K)	MOD07
D	vapor pressure deficit (Pa)	MOD07
g_r	radiative conductance (kg m ⁻² s ⁻¹)	$4 \epsilon_l \sigma T_a^3 / c_p$
$e_s(T)$	saturated vapor pressure at temperature, T (Pa)	MOD07
$I_{Po}(L)$	total PAR radiation at canopy depth L ($\mu\text{mol m}^{-2} \text{s}^{-1}$)	canopy radiative transfer model (see section 2.1.2)
$I_{Pb}(L)$	direct beam PAR at canopy depth L ($\mu\text{mol m}^{-2} \text{s}^{-1}$)	canopy radiative transfer model (see section 2.1.2)
$I_{Pd}(L)$	diffuse PAR at canopy depth L ($\mu\text{mol m}^{-2} \text{s}^{-1}$)	canopy radiative transfer model (see section 2.1.2)
$I_{No}(L)$	total NIR radiation at canopy depth L ($\mu\text{mol m}^{-2} \text{s}^{-1}$)	canopy radiative transfer model (see section 2.1.2)
$I_{Nb}(L)$	direct beam NIR at canopy depth L ($\mu\text{mol m}^{-2} \text{s}^{-1}$)	canopy radiative transfer model (see section 2.1.2)
$I_{Nd}(L)$	diffuse NIR at canopy depth L ($\mu\text{mol m}^{-2} \text{s}^{-1}$)	canopy radiative transfer model (see section 2.1.2)
$R_{s,i}$	incoming shortwave radiation above the canopy (W m ⁻²)	atmospheric radiative transfer model (see section 2.1.1)
$R_{s,o}$	outgoing shortwave radiation above the canopy (W m ⁻²)	atmospheric radiative transfer model and MCD43
$R_{l,i}$	incoming longwave radiation above the canopy (W m ⁻²)	MOD07 and MOD05
$R_{l,o}$	outgoing longwave radiation above the canopy (W m ⁻²)	MOD11
$R_{n,j}$	canopy net radiation (W m ⁻²); $j = Sun$ for sunlit leaf, and $j = Sh$ for shade leaf	atmospheric radiative transfer model, MCD43, MOD05, MOD07, and MOD11
$R_{n,soil}$	net radiation at soil surface (W m ⁻²).	equation (38)
R_n	sum net radiation of canopy and soil (W m ⁻²).	equation (38)
G_{soil}	soil heat flux (W m ⁻²).	equation (39)
R_{gPOT}	potential global solar irradiance (W m ⁻²)	Liu and Jordan [1960]
θ	solar zenith angle at time of MODIS overpass	MOD06
Ω	foliar clumping index	global clumping index map
L	leaf area index (m ² m ⁻²)	MCD15
L_c	canopy leaf area index (m ² m ⁻²)	MCD15
G	projection coefficient of unit foliage area on a plane perpendicular to the view direction	0.5 (assuming spherical leaf inclination angle distribution)
$f_{sun}(L)$	the probability of leaf area being irradiated by direct beam at canopy depth L [Gutschick, 1991]	equation (1)
k	extinction coefficient (= $G(\theta)/\cos\theta$) assuming spherical leaf angle distribution	$0.5/\cos\theta$
k_b	extinction coefficient for beam PAR or NIR for black leaves	$0.5/\cos\theta$
k'_{Pb}	extinction coefficient for beam and scattered beam PAR	$0.46/\cos\theta$ [de Pury and Farquhar, 1997]
k'_{Pd}	extinction coefficient for diffuse and scattered diffuse PAR	0.72 [de Pury and Farquhar, 1997]
k'_{Nb}	extinction coefficient for beam and scattered beam NIR	equation (12)
k'_{Nd}	extinction coefficient for diffuse and scattered diffuse NIR	equation (13)
k'_L	extinction coefficient for longwave radiation	0.78 [Goudriaan, 1977]
k_n	nitrogen extinction coefficient	k'_{Pb}

[67] **Acknowledgments.** G. Farquhar and D. de Pury gave constructive comments on their model. Martin Jung, Christian Beer, Jan Pisek, and Jing Chen kindly shared their products. In particular, we thank Deb Agarwal, Keith Jackson and Marty Humphrey for their support on the use of Microsoft Azure Cloud Computing Service. Larry Flanagan, Russ Scott, Gil Bohrer, Andrej Varlagin, Tomomichi Kato, and Rodrigo Vargas gave constructive comments on the manuscript. Y.R. was supported by NASA Headquarters under the NASA Earth and Space Science Fellowship Program (NNX08AU25H) and the Berkeley Water Center/Microsoft eScience project, and supported by Korea-Americas Cooperation Program through the National Research Foundation of Korea (NRF) funded by the Korean Ministry of Education, Science and Technology (2011-0030485). MODIS data processing was supported by Microsoft Azure cloud computing service. Data from the Tonzi and Vaira Ranches was supported by the Office of Science (BER), U.S. Department of Energy, grant DE-FG02-06ER64308. This work used eddy covariance data acquired by the FLUXNET community and in particular by the following networks: AmeriFlux (U.S. Department of Energy, Biological and Environmental Research, Terrestrial Carbon Program (DE-FG02-04ER63917 and DE-FG02-04ER63911)), AfriFlux, AsiaFlux, CarboAfrica, CarboEuropeIP, CarboItaly, CarboMont, ChinaFlux,

Fluxnet-Canada (supported by CFCAS, NSERC, BIOCAP, Environment Canada, and NRCan), GreenGrass, KoFlux, LBA, NECC, OzFlux, TCOS-Siberia, and USCCC. We acknowledge the financial support to the eddy covariance data harmonization provided by CarboEuropeIP, FAO-GTOS-TCO, iLEAPS, Max Planck Institute for Biogeochemistry, National Science Foundation, University of Tuscia, Universite Laval and Environment Canada and U.S. Department of Energy and the database development and technical support from Berkeley Water Center, Lawrence Berkeley National Laboratory, Microsoft Research eScience, Oak Ridge National Laboratory, University of California, Berkeley, and University of Virginia.
