For most current information:

THIS PUBLICATION IS OUT OF DATE.

Biological control

Biological control, using insects that feed exclusively on tansy ragwort, is effective in reducing weed populations and is recommended for areas where other controls are not practical or economical.

Usually it requires several years to establish an insect population large enough to reduce plant population. Eradication is not complete, but a dynamic balance between low density of the weed and control is expected.

The cinnabar moth is the most widely distributed biological control agent used against tansy ragwort. The black and red adult moths are most active in June and July. Yellow eggs, in clusters of about 40 each, are deposited on the undersides of the plant leaves. Larvae hatch from the eggs in 1 to 3 weeks and feed on leaves and buds. Growth and development of larvae requires 4 to 6 weeks. Full-grown larvae are about 1 inch long, and can be recognized by their black and yellow banded pattern of coloration. (See illustration.) On reaching full size, larvae change to pupae and are inactive until the adult emerges the next spring.

The tansy ragwort flea beetle is another biological control agent. Adult beetles, less than 1/8 inch long, tan in color, lay eggs in the crowns of the ragwort rosettes in the fall. Newly-hatched larvae burrow into and feed on roots of plants during winter and early spring and mature to the adult beetle form in late spring. Adults are relatively inactive until the shorter, cooler days of late summer or early fall when mating and egg laying commence again.

Both these insects are presently distributed in western Oregon and western Washington, and the object is to obtain complete coverage as soon as possible. Location and impracticality of other controls are of primary importance in choosing sites for future releases.

Because of the time required to establish insects for control, and since control is not complete once established, use of biological methods to control infestations found in eastern Washington, Idaho, and eastern and southern Oregon is not recommended.

Herbicides can provide complete control immediately; thus, infestations have no chance to spread.

Similar appearing plants

Two plants often confused with tansy ragwort are common tansy (Tanacetum vulgare) and common groundsel (Senecio vulgaris). Common tansy, often called "bitter buttons," "hind head," or "parsley fern," may grow to a height of 6 feet or more. It contains a poisonous oil called tanacetin. Because of the bitter taste of the plant, however, it is seldom eaten by livestock.

Common groundsel is an annual plant, growing 4 to 16 inches tall, with hollow stems. Leaves are alternate; lower leaves clasp the plant stem. All leaves are deeply lobed and toothed, but much smaller than tansy ragwort leaves. Flowers in each head have about 21 slender, black-tipped bracts at their base. Seeds are long and narrow, with a cluster of fine hairs longer than the seed attached to the upper end. It is seldom eaten by livestock.

What you can do

Sightings of tansy ragwort in eastern Washington and eastern and southern Oregon and Idaho have been limited to a few plants, usually less than five per sighting. If you find this weed invading new areas, you can check or prevent its spread by doing one of the following:

- If it is in the flowering stage, first, carefully cover the plant with a plastic bag to prevent seed spread. Then pull up the plant, pour fuel oil on it, and burn it in a safe place.
- If it is in the rosette or seedling stage, pull the plant or spray it with 2,4-D or dicamba, according to spray recommendations. Then report the sighting immediately to your county Extension agent or to the Department of Agriculture in your state.

Be sure to make note of the exact location of the sighting. Here are addresses and telephone numbers:

- Oregon State Department of Agriculture, Salem, Oregon (503) 378-3774
- Washington State Department of Agriculture, Olympia, Washington (206) 753-5046
- Idaho State Department of Agriculture, Boise, Idaho (208) 384-3240

If identification is uncertain, take a sample of the plant, including flowers, leaves and stems, to your Extension agent. County Extension offices are listed under County Government in the telephone directory for county-seat towns.
Diarrhea, nose, feces, and blood in stage, use 2,4-D amine, low-volatile ester. Poisoning include swelling, damages and enable the animal to survive. When tansy is small or in rosette they have a chance to flower and produce more seed. Spraying instructions: Spraying at the early bolting stage or later may not yield good control. Pulling the plant from going to seed, but the plant will not die. Flowering tansy ragwort has very distinct button-like heads. Leaves resemble a fern fan. The leaves, 5 to 9 inches long, are deeply lobed. Leaf color may vary from light to dark green. Tansy ragwort leaves and the blade region near the tip are deeply lobed. Leaf color may vary from light to dark green.

Chemical control

The most effective and economical herbicide for control of tansy ragwort is 2,4-D. Excellent control has been obtained by spraying the rosette stage of growth in early spring or midfall after fall rains have initiated new growth. For small spray equipment, use 2 to 3 fluid ounces of 2,4-D for each gallon of water. Wet the plants thoroughly for good control. Plants die slowly after being sprayed. Spray on warm and sunny days when rain is not expected within 4 to 6 hours.

Spraying instructions

1. Tansy ragwort seedling is most difficult stage to identify.
2.Oregon stage is the most effective time for spraying with 2,4-D.
3. Spraying at the early bolting stage or later may not yield good control. Pulling the plant from going to seed, but the plant will not die.
4. Flowering tansy ragwort has very distinct button-like heads. Leaves resemble a fern fan and are larger than those of tansy ragwort. Seedlings and rosettes are consumed before the flowering stage, since seedlings and rosettes are consumed before the flowering stage. Toxicity of tansy ragwort is reported to contain six different alkaloids, which accumulate in the liver and cause liver damage. All stages grow in the absence of the flowering stage, since seedlings and rosettes are consumed before the flowering stage. To remove tansy ragwort leaves and the blade region near the tip are deeply lobed. Leaf color may vary from light to dark green.

Larvae of the cinnabar moth can reduce tansy ragwort populations to low levels, areas where other controls are not practical or economical.

Common groundsel (Senecio vulgaris) flower head, as wide as most groundsel's. In some areas it is at or near the crest and is threatening to invade areas east of the Cascades and southern Oregon. Tansy ragwort is one of the first plants to invade cutover forest lands. It is not usually found in annually-tillied fields, but can invade irrigated or nonirrigated pastures, woodland pastures, unused lands, perennial seed fields, and is frequent in the fields in alfalfa fields.

Tansy ragwort is a biennial plant but, under favorable conditions, plants may live over as a perennial. Most seeds germinate in the fall, form a rosette the following year, and blossom the next year. Plants normally blossoms, produce seed, and die in the second year unless cut, pulled, or broken. Damage may result in regrowth and blossoming the third year; thus, it can be a perennial. Seeds may be viable in the soil 3 to 4 years, or even longer.

Tansy ragwort is a very conspicuous weed problem in western Oregon and Washington. In recent years, sightings east of the Cascades and in southern Oregon have increased; and it is a potential problem for eastern Oregon, Washington, and Idaho.

Tansy ragwort was introduced into the United States from Europe. The first reported introduction in Oregon was in 1992. Although the heaviest infestations of tansy ragwort in Oregon are along the coast range, it has succeeded in spreading across western Oregon, Washington, and up the western slopes of the Cascades, especially in heavily logged areas. In some areas it is at or near the crest and is threatening to invade areas east of the Cascades and southern Oregon.
Tansy ragwort, Senecio jacobaea L., is one of the more serious weed problems in western Oregon and Washington. In recent years, sightings east of the Cascades and in southern Oregon have increased; and it is a potential problem for eastern Oregon, Washington, and Idaho.

Tansy ragwort was introduced into the United States from Europe. The first reported observation in Oregon was in 1922. Although the heaviest infestations of tansy ragwort are in the coast range, it has succeeded in spreading across western Oregon and Washington and up the western slopes of the Cascades, especially in heavy-ged areas. In some areas it is at or near the crest and is threatening to invade areas east of the Cascades and southern Oregon. Tansy ragwort is one of the first plants to invade cutover forest lands. It is not usually found in annually-fertilized fields, but can invade irrigated or nonirrigated pastures, woodland pastures, unused lands, perennial seed fields, and is found occasionally in affable fields.

Tansy ragwort is found in the drier regions of Europe and Asia and in Siberia; therefore, it is believed that it can complete its life cycle successfully throughout most of the Northwest. It will survive under most soil moisture conditions, even the hot and dry summers of southern and eastern Oregon and Washington, and will overwinter successfully in areas where temperatures reach -20°F or lower.

Use of ragwort contaminated straw from western Oregon has resulted in tansy infestations on roadside improvement projects in eastern Oregon. Contaminated straw and hay brought in by hunters is a major carrier.

Lifecycle

Tansy ragwort is a biennial plant but, under some conditions, plants may live over as a perennial. Most seeds germinate in fall, form a rosette the following year, and blossom the next year. Plants normally blossom, produce seed, and die in the second year unless cut, pulled, or broken. Damage may result in regrowth and blossoming the third year; thus, it can be a perennial. Seeds may be viable in the soil 3 to 4 years, or even longer.

Tansy ragwort is a very conspicuous plant when it blooms. The daisy-like golden flowers have a long blossoming period. The rosette plants have irregular, lobed leaves with a visible blade region near the tip. The leaves, 5 to 9 inches long, are attached directly to the main stalk. Leaf color may vary from light green to dark green.

The plant spreads principally by seeds, and individual plants may have as many as 150 thousand seeds. Most of these seeds fall within a few hundred feet of the parent plant, but some are carried great distances by wind and water.

In the Pacific Northwest, cattle numbers east of the Cascades far exceed those west of the Cascades. The spread of this poisonous weed is from west of the Cascades and to southern Oregon would result in severe losses of livestock.

Toxicity

Tansy ragwort is not highly poisonous, but all parts of the plant are poisonous to cattle and horses and, to some extent, sheep. It is reported to contain six different alkaloids, which accumulate in the liver and cause liver damage. All growth stages and all parts of the plant contain roughly the same alkaloid concentration per unit of plant weight. Fortunately, tansy ragwort plants are not very palatable; therefore, the large plants usually are not eaten. Poisoning often occurs when seedlings are ingested accidentally by cattle and horses in a pasture situation. Small seedlings are intermixed with desirable forage, and livestock cannot distinguish between the seedlings and desirable forage. Contaminated hay causes poisoning since the dry weed is consumed readily with the rest of the hay.

Removal of tansy ragwort from the diet, accompanied by feeding high-quality forage and grain, may stop subsequent liver damage and enable the animal to survive. Complete recovery is rare. Symptoms of the poisoning include swelling, inflammation of membranes around eyes and nose, diarrhea, blood in feces, rough cost, excessive fluid in the body cavity, and a droopy appearance.

Chemical control

The most effective and economical herbicide for control of tansy ragwort is 2,4-D. Excellent control has been obtained by spraying the rosette stage of growth in early spring or midfall after fall rains have initiated new growth. For small spray equipment, use 2 to 3 fluid ounces of 2,4-D for each gallon of water. Wet the product label for grazing restrictions on roadside improvement projects in the Northwest. It will survive under most soil moisture conditions, even the hot and sunny days when rain is not expected within 4 to 6 hours. Controlling tansy ragwort with 2,4-D is less effective after the plants start sending up flowering stalks. It may be necessary to spray the plants twice or more, and days after the first herbicide application, to spray plants missed by the first application. Spray rosettes and seedlings at any time when the plants are actively growing. After the flower stalks start to elongate, other herbicides must be used to obtain control, usually combined with 2,4-D.

Spraying instructions

1. When tansy is small or in rosette stage, use 2,4-D amine, low-volatility ester (LVE) or emulsifiable acid form. Apply to 1 to 3 pounds of active material per acre. If formulation is 4 pounds active per gallon, then use 1 to 3 quarts per acre in 20 or more gallons of water. When the ragwort plants are small, use lower rates. Use 2 to 3 fluid ounces of material for each gallon of water in handsprayer.

2. When tansy is large or when flower stalk has elongated, use dicamba (Ben- veil) or dicamba plus 2,4-D. Apply 1 pound active (1 quart) of dicamba or 0.5 to 1 pound dicamba plus 2 to 3 quarts of 2,4-D per acre, in 20 or more gallons of water.

Always follow label instructions. Check the product label for grazing restrictions on roadside improvement projects in the Northwest.

Even though sheep are not completely immune to the toxic effects of tansy, sheep grazing is an effective way to control tansy ragwort if the animals are confined by fences to the ragwort-infested areas. Confine the sheep in these areas for several successive weeks. Intensive grazing of ragwort in several areas for a number of years results in the absence of the flowering stage, since seedlings and rosettes are consumed before they have a chance to flower and produce more seed.
Tansy ragwort, Senecio jacobaea L., is one of the more serious weed problems in western Oregon and Washington. In recent years, sightings east of the Cascades and in southern Oregon have increased; and it is a potential problem for eastern Oregon, Washington, and Idaho.

Tansy ragwort was introduced into the United States from Europe. The first report of observation in Oregon was in 1922. Although the heaviest infestations of tansy ragwort are in the coast range, it has succeeded in spreading across western Oregon, Washington, and in the western slopes of the Cascades, especially in heavily logged areas. In some areas it is at or near the crest and is threatening to invade areas east of the Cascades and southern Oregon. Tansy ragwort is one of the first plants to invade cutover forest lands. It is not usually found in annually-tilled fields, but can invage irrigated or nonirrigated pastures, woodland pastures, unused land, perennial seed fields, and is found occasionally in alfalfa fields.

Tansy ragwort is found in the drier regions of Europe and Asia and in Siberia, therefore, it is believed that it can complete its life cycle successfully throughout most of the Northwest. It will survive under most soil moisture conditions, even the hot and dry summers of southern and eastern Oregon and Washington, and will overwinter successfully in areas where temperatures reach -20°F or lower.

Use of ragwort contaminated straw from western Oregon has resulted in tansy infestations on roadside improvement projects in southern Oregon. Contaminated straw and hay brought in by hunters is a major carrier.

Lifecycle

Tansy ragwort is a biennial plant but, under some conditions, plants may live over as a perennial. Most seeds germinate in the fall, form a rosette the following year, and blossom the third year; thus, it can be a perennial. Seeds may be viable in the soil 3 to 4 years, or even longer.

Tansy ragwort is a very conspicuous plant when it blooms. The daisy-like golden flowers have a long blooming period. The rosette plants have irregular, lobed leaves with a visible blade region near the tip. The leaves, 5 to 9 inches long, are attached directly to the main stalk. Leaf color may vary from light to dark green. The plant spreads principally by seeds, and individual plants may have as many as 150 thousand seeds. Most of these seeds fall within a few hundred feet of the parent plant, but some are carried great distances by wind and water.

In the Pacific Northwest, cattle numbers east of the Cascades far exceed those west of the Cascades. The spread of this poisonous weed to areas east of the Cascades and to southern Oregon would result in severe losses of livestock.

Toxicity

Tansy ragwort is not highly poisonous, but all parts of the plant are poisonous to cattle and horses and, to some extent, sheep. It is reported to contain six different alkaloids, which accumulate in the liver and cause liver damage. All growth stages and all parts of the plant contain roughly the same alkaloid concentration per unit of plant weight. Fortunately, tansy ragwort plants are not very palatable; therefore, the large plants usually are not eaten. Poisoning often occurs when seedlings are ingested accidentally by cattle and horses in a pasture situation. Small seedlings are contaminated with desirable forage, and live stock cannot distinguish between the seedlings and desirable forage. Contaminated hay causes poisoning since the dry weed is consumed readily with the rest of the hay.

Removal of tansy ragwort from the diet, accompanied by feeding high-quality forage and grain, may stop subsequent liver damage and enable the animal to survive. Complete recovery is rare. Symptoms of the poisoning include swelling, inflammation of membranes around eyes and nose, diarrhea, blood in feces, rough coat, excessive fluid in the body cavity, and a droopy appearance.

Chemical control

The most effective and economical herbicide for control of tansy ragwort is 2,4-D. Excellent control can be obtained by spraying the rosette stage of growth in the early spring or midfall. Flowering tansy ragwort plants are small and economical. Use 1 to 2 fluid ounces of 2,4-D for control of tansy ragwort. Weed plants can be killed by spraying with 3 pounds of active material per acre. Use 2 to 3 quarts per acre in 20 gallons of water. When the ragwort is small, use lower rates. Use 2 to 3 fluid ounces of material for each gallon of water spray.

When tansy is large or when flowering has been initiated, use dicamba (Benomyl or dicamba plus 2,4-D). Apply 1 pound (1 quart) of dicamba or 0.5 to 1 pound dicamba plus 2 to 3 quarts of 2,4-D per acre, in 20 or more gallons of water.

Always follow label instructions. Check the product label for grazing restrictions and information about susceptibility of each material. These materials will injure or kill clovers.

Even though sheep are not completely immune to the toxic effects of tansy, sheep grazing is an effective way to control tansy ragwort if the animals are confined by fences or to the ragwort-infested areas. Grazing sheep in these areas for several successive years is an effective way to completely eradicate this species from these areas for a number of years results in the elimination of the flowering stage, since the flowers and seed pods are consumed before they have a chance to flower and produce more seed.

Spraying instructions

When tansy is small or in rosette stage, use 2,4-D amine, low-volatile ester.
## Biological control

Biological control, using insects that feed exclusively on tansy ragwort, is effective in reducing weed populations and is recommended for areas where other controls are not practical or economical. Usually it requires several years to establish an insect population large enough to reduce plant population. Eradication is not complete, but a dynamic balance between the density of the weed and control is expected.

The cinnabar moth is the most widely distributed biological control agent used against tansy ragwort. The black and red adult moths are most active in June and July. Yellow eggs, in clusters of about 40 each, are deposited on the undersides of the plant leaves. Larvae hatch from the eggs in 1 to 3 weeks and feed on leaves and buds. Growth and development of larvae requires 4 to 6 weeks. Full-grown larvae, 8 to 12 inches long, feed on the leaves. They pupate in the soil; adult moths emerge about 4 to 5 weeks later. The cinnabar moth, an annual, grows to a height of 8 inches tall, with narrow triangular leaves. Both larvae and adults feed on the plant. All leaves and stalks are divided into long, narrow, flat, toothed, fern-like segments which hang down. The cinnabar moth is effective in reducing weed populations and is recommended for areas where other controls are not practical or economical.

Biological control using insects that feed exclusively on tansy ragwort is effective in reducing weed populations and is recommended for areas where other controls are not practical or economical. Usually it requires several years to establish an insect population large enough to reduce plant population. Eradication is not complete, but a dynamic balance between the density of the weed and control is expected.

## Herbicides

Herbicides can provide complete control immediately; thus, infestations have no chance to spread.

### Similar appearing plants

Two plants often confused with tansy ragwort are common tansy (Tanacetum vulgare) and common groundsel (Senecio vulgaris). Common tansy has a large, yellow head; the "bitter buttons," "hind head" or "parsley fern," may grow to about 5 feet or more. It contains a poisonous oil called tansyin. Because of the bitter taste of the plant, however, it is not eaten by livestock.

Common groundsel is an annual, growing to about 8 inches tall, with narrow elongated leaves. Leaves are about 1 inch long, and can be recognized by their black and yellow banded pattern of coloration. On reaching full size, larvae pupate and are inactive until the next spring.

The tansy ragwort flea beetle feeds on the undersides of the biological control agent, leaves less than 1/2 inch long, tan in color, have the crowns of the leaves mostly green, and are soft. Newly-hatched beetles are brown and feed on roots or stems during late summer and early spring. They form in late summer. Adults are red, inactive and about 1/8 inch long. Larvae of late summer emergence are often dispossessed. They are about 3/4 inch long and have 4 narrow, black-tipped bracts at their base. Seeds are long and narrow, 3I LI8RAy 76.

**What you can do**

If you find this weed invading new areas, you can check or prevent its spread by doing one of the following:

- **If it is in the flowering stage, first, carefully cover the plant with a plastic bag to prevent seed spread.** Then pull up the plant, pour fuel oil on it, and burn it in a safe place.

- **If it is in the rosette or seedling stage,** pull the plant OR spray it with 2,4-D or dicamba, according to spray recommendations. Then report the sighting im- mediately to your county Extension agent or to the Department of Agriculture in your state.

Be sure to make note of the exact location of the sighting. Here are addresses and telephone numbers:
