SPAWNING FISH SURVEYS IN COASTAL  
WATERSHEDS, 1971 1/

GENERAL INFORMATION

Spawning fish surveys on index areas of Oregon coastal rivers and tributaries are made annually by personnel of Coastal Rivers Investigation, Fish Commission of Oregon. Annual peak counts of spawning salmon in the survey areas provide data for computing an index of the escapement into a coast-wide "fish-per-mile" figure for each species. Trends in abundance of spawning salmon are noted by comparing these data over a period of years. This report presents peak counts for 1971-72 and makes comparisons with similar data from previous years.

The earliest spawning fish surveys were established 25 years ago, and others were added as needed to form a coastwide sampling program. This year the survey project was substantially modified. Surveys that were not representative because of lack of suitable habitat, became inaccessible because of changing road use, or could not be adequately surveyed for physical reasons were eliminated. Those surveys that remain represent our current concept of good spawning streams. The net result of eliminating the surveys with poor spawning gravel was to slightly raise the fish-per-mile counts. Statistical analysis using the t-test for paired observations (Dixon and Massey, 1957) indicated that in the cases of fall chinook, coho and auxiliary chum counts, the mean fish-per-mile counts were raised significantly at the 99% level of confidence (t values were 8.83, 5.82, and 6.51, respectively).

---

1/ This work was partially supported by PL 89-304 funds.

Since the value of these surveys is to determine trends, the next statistical test was to determine if dropping certain of the surveys caused any change in the trends. Linear regressions of the new fish-per-mile counts were run against the initial counts and the square of the correlation coefficient was used to judge any changes (Li, 1957). For chinook 94% of the variations in the new average could be accounted for by the variations in the previous counts, while for coho 99% and for chum 96% of the variability is explainable in the same manner. With this result, it appears that dropping some of the surveys had no appreciable impact on the trends.

Present annual survey distances are 27.5 miles for fall chinook, 7.5 miles for chum, and 39.0 miles for coho. An additional 17.1 miles of stream are surveyed in the Tenmile lakes system to provide the data base for an annual estimate of the population and egg deposition. The spring chinook surveys were suspended because the counts were so low no meaningful trends were evident.

Index areas were often surveyed more than once to ensure that counts were made near the peak of the run. Variability in the timing of the spawning migrations between streams, volume and duration of flood flows and silt load frequently caused aborted surveys that had to be rescheduled and occasionally resulted in inadequate surveys on some standard index areas.

The fall Creek (Alsea River) fall chinook survey was the only survey that was retained but not counted this year. Prolonged high water and heavy silt loads made it impossible to identify the chinook among the tremendous number of coho that traverse this section of stream to the Fish Commission's Fall Creek Hatchery.

Coastal Rivers personnel made 203 surveys encompassing 175 miles during the 1971-72 spawning season (Table 1). The surveys represent about a 40% decrease over the effort of the previous year. Surveys started on October 29, 1971, and continued through January 3, 1972.

Since 1958, survey data have been exchanged with the Oregon Game Commission to avoid duplication of some surveys. The Game Commission biologists provided data from two standard surveys on Nehalem River tributaries, one on a Coos River tributary and two on tributaries of the Coquille River.

#### Influence of Weather on the 1971-72 Spawning Fish Surveys

Weather was fairly typical during the fall of 1971. Freshets were spaced such that most surveys were completed between storms. However, beginning in December and continuing through January, above normal rainfall kept the streams high and turbid. Consequently, some of the coho surveys were accomplished under less than ideal conditions, and fewer than normal resurveys were possible. The intense storm of early January made further surveying impractical.

#### Influence of Human Activities on 1971-72 Spawning Fish Surveys

Activities of the Fish Commission and Oregon State University have affected the validity of the counts on some of our standard survey areas.

The fall chinook counts on the Siletz and Alsea rivers have been affected by the activities of the Fish Commission. Ladders and large returns of coho to the hatcheries have made it impossible to make usable index counts in three of the survey areas.

A ladder constructed at the upper end of the fall chinook survey area on Sunshine Creek of the Siletz River in 1963 has allowed fish, which normally would have spawned in the survey area, to spawn farther upstream.

Table 1. Number of Spawning Fish Surveys and Distances Surveyed by Coastal River Staff During the 1971-72 Spawning Season

Total	58	58.7	27	16.6	118	99.5	203	20.8

1/ Concurrent with fall chinook survey.

Since installation of the ladder, the counts have averaged only 70% of the counts that were made in the previous 9 years. Since this survey area represents 40% of the index area for the Siletz River, the change has caused a false decline in the trend for the whole river system of approximately 8%.

The recent increase in returns of coho to the Rock Creek Hatchery has resulted in large numbers of stray coho utilizing the chinook survey area on North Rock Creek for spawning. An overabundance of coho in the survey area was first noted in 1965. Large masses of fish in each pool have made it impossible to count all the live chinook present. The count of chinook carcasses is undoubtedly low because some are buried by the digging of the coho. The superimposition that is occurring in the survey area has undoubtedly been detrimental to the chinook. Since this is a regular occurrence, the survey area is no longer indicative of the chinook abundance in the Siletz River.

Similar conditions occur in the standard survey on Fall Creek on Alsea River. A tremendous number of coho returning to the hatchery now traverse the survey area during the fall chinook spawning period. Considerable numbers of these coho spawn in the survey area causing superimposition on chinook eggs already in the gravel, as well as competing with female chinook for the more favorable redd sites. This has resulted in counts in the survey area being no longer indicative of the general conditions in the watershed.

The chum salmon counts on Whiskey Creek are no longer indicative of the run into that system. Oregon State University has constructed a trap in our survey area and takes eggs for their hatchery. Thus, the distribution, abundance, and sex and age data are no longer representative.

## RESULTS

### Fall Chinook Salmon

The count of fall chinook in six coastal rivers was 29 fish per mile which was 8 fish per mile below the 19-year average (1952-70) (Table 2). The number of fish per mile between river systems ranged from 26 on the Yaquina and Alsea rivers to 55 on the Nestucca River. All the rivers except the Alsea had fish-per-mile counts lower than their long-term averages.

The trend counts show a rise in escapement level after cessation of commercial fishing in the rivers in 1956 followed by about a 10-year period of stability (Figure 1). Although the counts dropped somewhat in 1968, 1969, and 1971, the fluctuations are within expected ranges.

The counts in the auxiliary survey areas on the Siuslaw and Coquille rivers paralleled those of the standard areas by showing a decline from the previous year's record high to a level slightly less than average.

Peak counts for each survey area are tabulated in Appendix tables 1-8.

### Coho Salmon

The peak count of coho salmon in eight coastal drainages was 32 fish per mile, which equalled the 21-year average. Counts ranged from 13 fish per mile on the Nestucca River to 58 fish per mile on the Yaquina River (Table 3). The counts for each stream system ranged from 49 to 171% of their 1950-70 averages.

The coastwide average of the peak fish-per-mile counts represent the second year of improvement from the very low count of 1969 (Figure 2). It also represents a 45% improvement over the brood year which produced it which is encouraging since the 1968 spawning season was severely affected by long periods of ice and snow which minimized areas available for spawning. The count of jack coho was two fish per mile which equalled that of the 2 previous years but was only half the long-term average.

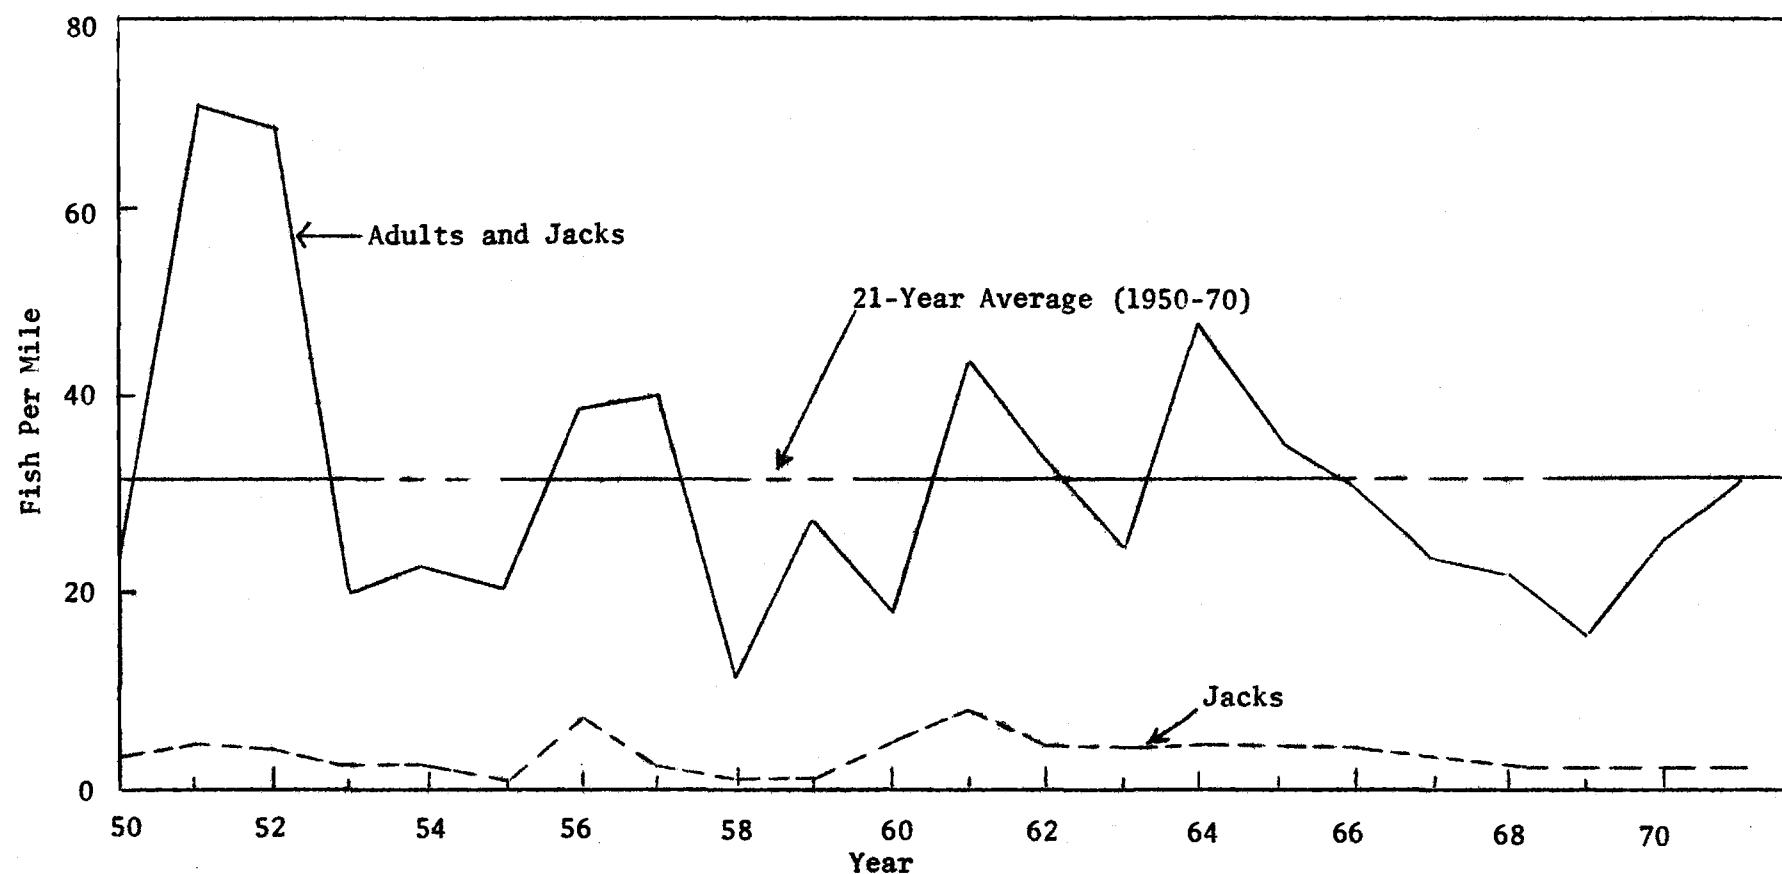

Figure 2. Average Number of Coho Per Mile in Standard Survey Areas of Eight Coastal Rivers, 1950-71

The peak counts of coho in the standard and auxiliary survey areas in tributaries of Tenmile Lake were 71 and 287 fish per mile, respectively (Table 4). These counts were 27 and 113% of the average of the standard and auxiliary counts, respectively. These data can be used to estimate total escapement, based upon a population estimate study completed in 1955-56 (Morgan and Henry, 1959). The resulting estimates indicate a fairly static escapement level between 1960 and 1967 with a sharp decline in 1968 which equaled the record low of 1959 (Figure 3). Since the lake was chemically treated by the Game Commission in 1968 to remove populations of warm-water fish, drastic changes have occurred in the coho population. The returns of jacks in 1969 and adults in 1970 were the result of rearing Tenmile lakes stock coho in a hatchery and releasing them into the system as smolts.

The 57,000 jacks that returned in 1970 and the 33,500 adults that returned in 1971 were the progeny of natural spawning 1968-brood stock. As juveniles, they had the advantage of living in a lake environment with substantially reduced predation and competition. The estimate of 57,000 jacks is the highest since the escapements have been calculated, and the 33,500 adults represented the second highest estimate since they began 17 years ago.

The adult escapement produced an estimated deposition of 61.2 million eggs which was 185% of the 1955-70 average (Table 5) and highest since 1955.

The 1971 jack run estimated at 10,500 was the result of a low number of females in the 1969 spawning escapement and possible adverse environmental factors in the tributary streams.

Peak counts for each survey area are tabulated in Appendix tables 9-18.

1955-70 Average	16,300		24,100	40,400	33.1

1/ Estimated from the average female-to-male ratio of 1957-64.

2/ Based on fecundity of 3,000 eggs per female.

3/ Confidence limits (95%) were  $\underline{N} = 11,800$  and  $\bar{N} = 18,400$ .

Chum Salmon

The peak count of chum salmon in three drainage basins was 96 fish per mile (Table 6). This was 64 fish-per-mile lower than the 18-year average and was intermediate between the counts for 1967 and 1968, the years in which they were produced (Figure 4). The runs were down in all three river systems. OSU was only able to take about 280,000 eggs of the 750,000 they had scheduled from Whiskey Creek.

The auxiliary fish-per-mile count on Tillamook Bay tributaries was 390 fish which was 43 fish-per-mile higher than the 11-year average. The 1971 fish-per-mile count was distinctly higher than either of the brood years that produced it.

A strong trend on a 4-year cycle can be noted in the standard survey counts. This trend is also reflected by the auxiliary fish-per-mile counts in 1963 and 1967. The relative low counts in the standard areas in 1971 follow the relative low counts of 1955, 1959, 1963, and 1967. Although widely fluctuating, the counts show evidence of stabilizing at a low level during the 1960's after the decline of the 1950's.

Peak counts for each survey area are tabulated in the Appendix tables 19-22.

Age, Size, and Sex Composition of 1971 Chum Salmon Run

As in previous years, attempts were made to sample dead chum salmon for age, length, and sex by collecting data from the first 50 dead fish encountered in each river system. Because of the poor escapement and flood conditions in the major rivers, we were only able to collect 304 samples, mainly from Coal Creek of the Kilchis River.

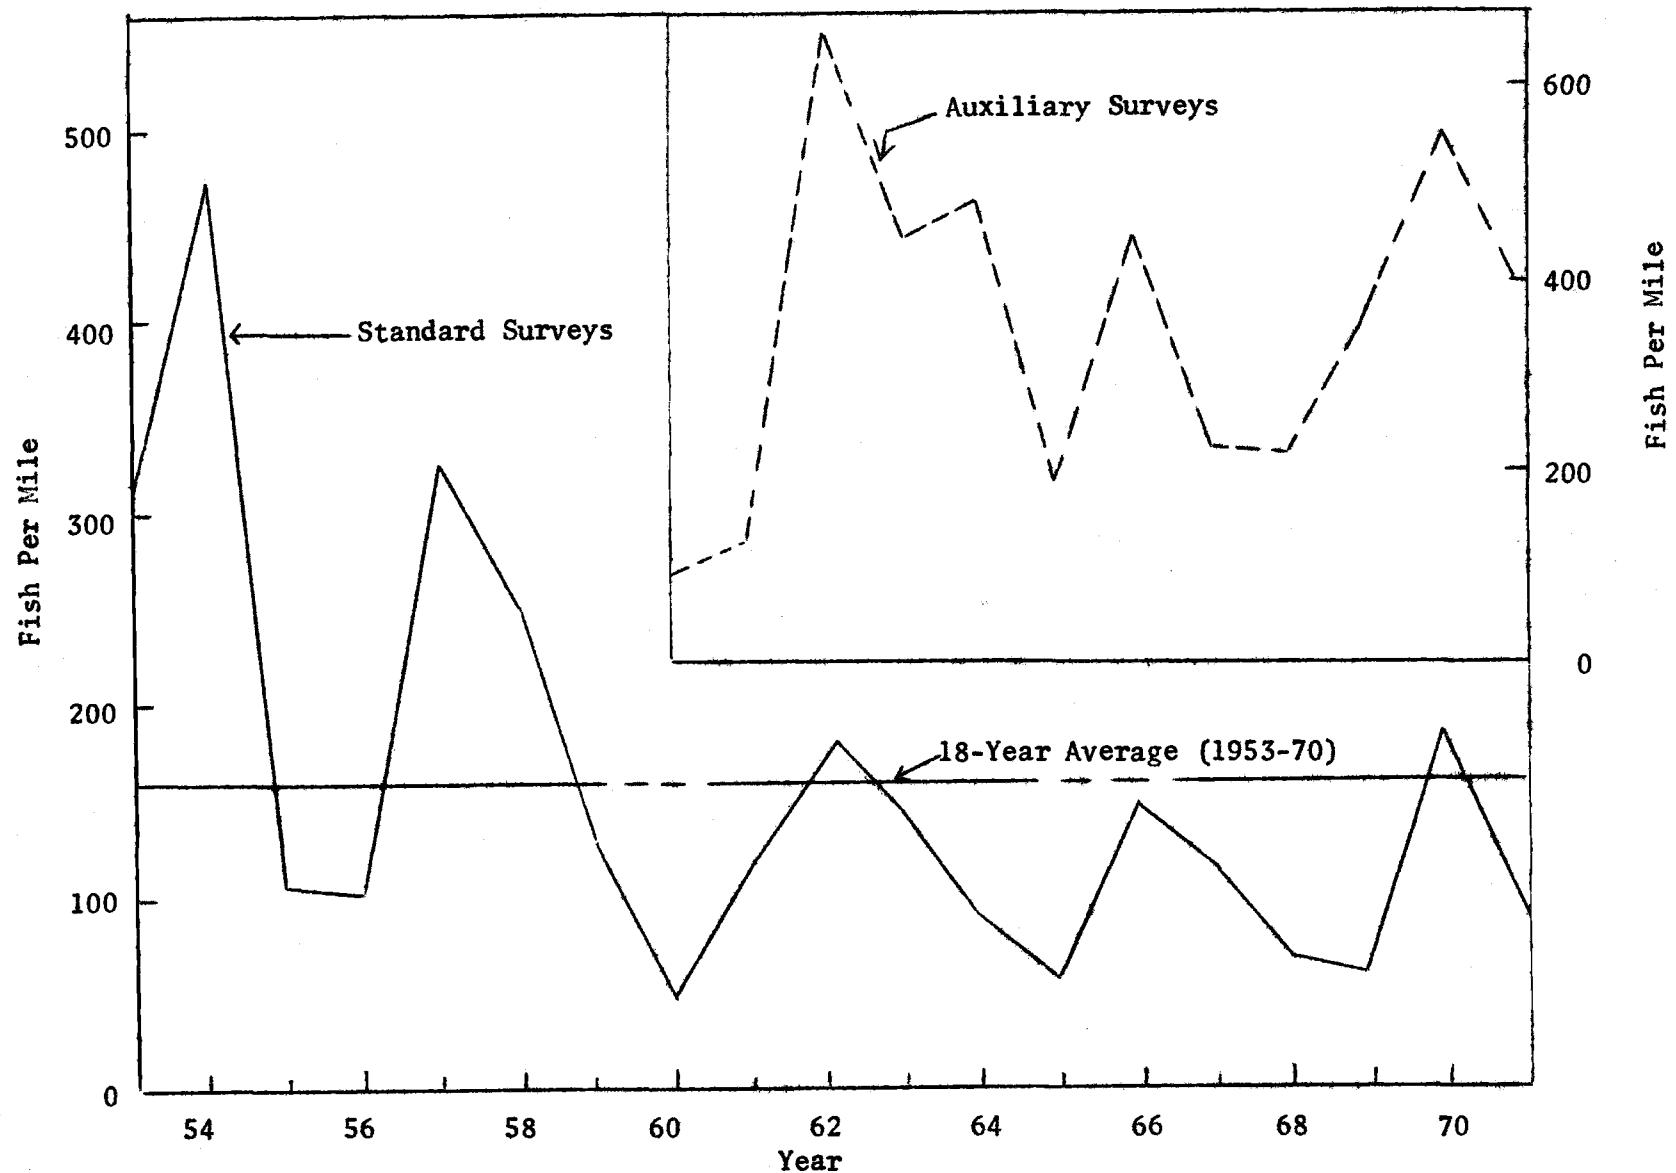

Figure 4. Average Numbers of Chum Per Mile in Standard and Auxiliary Survey Areas of Three Coastal Drainages, 1953-71

The length of fish by age and sex was within the limits found in previous inventories except that 4th year females averaged slightly shorter in length (Table 7). Females ranged in size from 23 to 30.5 inches, while males were from 25 to 32.5 inches.

The sample was predominantly females this year in both year classes. This may have been due to differential die-off time.

The run was nearly equally split between 3rd- and 4th-year fish (Table 8, Figure 5). In general, the fish were smaller, substantiating the hypothesis that 1966-68 brood chum have experienced poor growing conditions in the ocean.

#### SUMMARY

The surveys of spawning fish in coastal rivers in 1971 indicate that stocks of chum salmon remain at a low, although apparently stabilized level. Fluctuations are probably the result of year-class survival and age at maturity, rather than continued decline of the species.

The fall chinook index of abundance was only 78% of the long-term average. The counts were low in all but one of the standard survey watersheds and in both auxiliary survey river systems so it can be presumed that the surveys accurately reflected a decreased escapement.

The coho index of abundance equaled its long-term average indicating a generally adequate spawning density. The Tenmile Lakes run looks particularly promising because a near record number of eggs were deposited by the escapement this year. However, the low number of jacks returning this year suggests the number of adults returning next year will be considerably reduced.

## **APPENDIX TABLES**

### Appendix Tables

The tables in this appendix are presented first by species and within species by watershed from north to south. The peak counts and fish per mile figures may not agree precisely with reports from years prior to 1971 because of a reduction in the number of surveys, and deletion of spring chinook surveys entirely.

Within the tables, the figures in parentheses are the jack salmon counts and these figures are included in the totals. In some instances, the standard survey could not be made. In these cases the numbers of fish were estimated. This was done by determining the ratio of total fish which were seen in that particular survey during the preceding 2 years to the total fish seen in all the other streams in that system during the same period. That ratio was applied to the total of the other surveys in the drainage for the year in question and the resulting figure was assumed as the number of fish which should have been seen in the survey area. That figure was then entered into the calculations as if the survey was done.

The supplemental surveys are included for reference. Data from these surveys are not used in computing fish-per-mile values because, in most cases, the supplemental surveys were started at a later date. The Tenmile Lake auxiliary survey provides the data for the actual population estimate.

-------	-----

<sup>1/</sup> Estimated total run to Whiskey Creek made by OSU.  
Run in excess of OSU needs was allowed to spawn  
above rack (approximately 750,000 eggs taken in  
1969 and 1970; approximately 280,000 eggs taken  
in 1971).
